THE MINISTER OF HEALTH ON HIS PLANS.—Under the auspices of the People's League of Health, a deputation waited on Mr. Neville Chamberlain on Jan. 27th. The deputation was introduced by Viscount Burnham, and its object was to submit to the Minister the resolutions passed at the Conference convened by the League, held at the British Empire Exhibition, Wembley, last May. The members of the deputation included: Prof. J. G. Adami, Sir W. Arbuthnot Lane, Sir Harry Baldwin, Dr. H. Scurfield, Sir Leonard Rogers, Sir William Simpson, Dr. A. F. Tredgold, Mr. C. J. Bond, Prof. H. R. Kenwood, Colonel S. Lyle Cummins, Dr. Jane Walker, Prof. F. E. Wynne, Prof. G. M. Robertson, Prof. W. E. Dixon, Lieut.-Col. F. E. Fremantle, Mr. E. B. Turner, Mrs. Scharlieb, M.D., and Miss Olga Nethersole. The Minister of Health, replying to the deputation, said that the department had already issued a pamphlet on diet. He doubted whether a Government department could properly undertake the issue of popular leaflets which must necessarily be in a form open to criticism by specialists. But he contemplated that further pamphlets would be issued by the department which might be made a basis of popular leaflets prepared by more suitable bodies. He would give further consideration to the question. He was advised that the public were getting far more careful about the kinds of prepared foods that they gave to children; but he agreed that possibly something more needed to be done by regulation, and he was considering the framing of regulations on this subject. He proposed

to accept generally the recommendations of the Food Preservatives Committee, which would be circulated in draft so that the interests concerned could make out any case they had against them. In view of the many Government measures urgently requiring to be passed through, he doubted whether it would be politic to introduce legislation for the abatement of the smoke nuisance this session, but he hoped to secure it an early place in the Government programme next year. As to provision of facilities for the early treatment of mental cases, the fact that he had himself prepared a Bill when previously in office was an earnest of his intentions in this matter. He was informed that the Board of Education were about to make special provision for dealing with children who had suffered from encephalitis lethargica. The securing of better coördination of hospital services was an aim with which he was in entire sympathy. The reform of the Poor-law, which was essential to this object, would be dealt with by the Government as soon as possible. He quite recognised the risk of the spread of tuberculosis by adults suffering from the disease. He thought that it would be better to remove the source of infection from the children rather than the children from the source of infection, because if the source of infection was not removed though it might not affect children it would probably infect somebody else. Many local authorities had in private Bills taken power to remove tuberculous cases compulsorily, and he was prepared to give general powers to local authorities in amending the Public Health Bill which he contemplated introducing as early as possible. That Bill would be a preliminary to the consolidation of the Public Health Acts, and he hoped that it might be possible to get both these measures through in the coming session. He also hoped that if not this session, at any rate next, he would be able to get through a Bill amending the Midwives Act. The Home Office at present had a committee under the chairmanship of Mr. Justice Tomlin considering the subject of amendment to Part I. of the Children Act, 1908, and he hoped that legislation on this subject also would be possible at an early date. He associated himself with the resolution, congratulating Miss Nethersole and her helpers on the success of the Conference.

Medical Diary.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, Piccadilly, W.
THURSDAY, Feb. 5th.—4.30 P.M. *Papers to be read:*
H. M. Carleton: Growth, Phagocytosis, and other Phenomena in Tissue Cultures of Foetal and Adult Lung. (Communicated by Sir Charles Sherrington, O.M., P.R.S.) F. W. Fox and J. A. Gardner: The Origin and Destiny of Cholesterol in the Animal Organism. Part XIV.—The Cholesterol Metabolism in Normal Breast-fed Infants. (Communicated by Sir Walter Fletcher.) H. H. Thomas: The Caytoniales. A New Group of Angio-sperous Plants from the Jurassic Rocks of Yorkshire. (Communicated by Prof. A. C. Seward.) Winifred Branchley and H. G. Thornton: The Relation Between the Development, Structure, and Functioning of the Nodules on *Vicia Faba* as Influenced by the Presence or Absence of Boron in the Nutrient Medium. (Communicated by Sir John Russell.)—*Papers to be read in title only:* A. S. Rau, F. W. R. Brambell, and J. B. Gatenby: Observations on the Golgi Bodies in the Living Cell. (Communicated by Prof. J. P. Hill.) V. Nath: Cell Inclusions in the Oögenesis of Scorpions. (Communicated by Prof. J. Stanley Gardiner.) L. J. Harris: The Combination of Proteins, Amino-acids, &c., with Acids and Alkalis and their Combining Weights, as Determined by Physico-chemical Measurements. (Communicated by Sir Frederick Hopkins.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W. MEETINGS OF SECTIONS.

Tuesday, Feb. 3rd.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)

Cases:

Mr. W. H. Ogilvie: (1) Case of Paralytic Dislocation of the Hip-joint. (2) Case of Rickets with Unusual Deformities.
Mr. R. C. Elmslie: Two Cases of Scoliosis with Paraplegia.
Mr. H. A. T. Fairbank (President): (1) Case of Unilateral Imperfect Formation of Hip-joint: Subluxation with Spontaneous Recovery. (2) Specimen, &c., of Unusual Osteoma from Case of Multiple Exostoses.

Other cases will be shown.

Will members wishing to show cases please send their notes to the hon. secretary, Mr. P. Jenner Verrall, 116, Park-street, W.

PATHOLOGY: at 8.30 P.M., at the National Institute for Medical Research, Hampstead, N.W. 3.

Demonstrations:

J. Brownlee: Charts Illustrating Changes in Immunity with Age.

A. Eidinow: The Effect of Irradiated Blood on Hæmo-bactericidal Power.

H. H. Dale, F. M. Durham, and J. E. Marchal: The Effect of "Bayer 205" on Trypanosomes.

J. Smiles: The Action of Light on Bacteria.

J. E. Barnard: A Method of Demonstrating the Development of Young Colonies with High Powers.

H. W. Dudley and O. Rosenheim: Demonstration of Spermine Phosphate from Various Tissues.

W. Mair: A Peculiar Reaction to Filtrates of Pneumococcal Cultures.

S. R. Douglas: Some Remarks on Möllgaard's Chemotherapeutic Treatment of Tuberculosis.

Communications:

W. J. Purdy: The Temperature of Normal Rabbits.

P. Hartley: Further Observations on the Role of the Ether-soluble Constituents of Serum in Certain Serological Reactions.

Wednesday, Feb. 4th.

SURGERY

ANÆSTHETICS

MEDICINE

OBSTETRICS &

GYNÆCOLOGY

PATHOLOGY

Speakers:

Sir Charles Gordon-Watson and Mr. E. C. Lindsay (Surgery), Dr. F. E. Shipway (Anæsthetics), Lord Dawson of Penn (Medicine), Mr. J. Prescott Hedley (Obstetrics), and others.

N.B.—If necessary, this discussion will be adjourned to Friday, Feb. 6th, at 8.30 P.M.

Friday, Feb. 6th.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)

Cases will be shown by Mr. H. M. Wharry, Mr. Herbert Tilley, Mr. Norman Patterson, Mr. H. Bell Tawse, Dr. W. H. Kelson, Mr. F. J. Steward, Mr. T. B. Layton, Dr. T. B. Jobson.

Saturday, Feb. 7th.

OTOLOGY: at 10.30 A.M. (Cases at 9.45 A.M.)

Cases will be shown.

Demonstration:

Mr. Lionel Colledge: Kinematograph Pictures of Cases of Facial Paralysis Treated by Nerve Anastomosis.

Paper:

Mr. G. J. Jenkins: Septicæmia as a Complication of Middle-ear Infection.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Feb. 2nd.—5 P.M., Prof. Zachary Cope: Extravasation of Bile.

WEDNESDAY.—5 P.M., Prof. H. P. Winsbury White: The Pathology of Hydronephrosis.

FRIDAY.—5 P.M., Prof. A. H. Todd: Syphilitic Arthritis.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

MONDAY, Feb. 2nd, to SATURDAY, FEB. 7th.—WEST

LECTURE HALL, Royal Society of Medicine, 1, Wimpole-street. Lecture arranged by the Fellowship of Medicine and open to all members of the profession. Monday, Feb. 2nd, 5.30 P.M., Mr. Arthur Giles: The Operative Treatment of Uterine Displacements.—COMBINED COURSE IN DISEASES OF CHILDREN, Paddington Green, Victoria Hospital and Children's Clinic. Two sessions daily.—LONDON LOCK HOSPITAL. Comprehensive Course. Clinical work daily and lectures at Dean-street Monday, Tuesday, Thursday, and Friday.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN. Demonstrations daily in the various departments. Pathological demonstrations arranged for and Tuesday and Thursday special lectures. Tickets for this particular course from the Fellowship.—LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (Tropical Section, Endsleigh Gardens). Tuesday and Thursday, 2 P.M. Clinical Demonstration by Dr. G. C. Low and Dr. P. Manson-Bahr.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Feb. 2nd.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Mr. Bishop Harman: Eye Dept.

TUESDAY.—11 A.M., Dr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Banks-Davis: Throat, Nose, and Ear Dept.

WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Dowling: Skin Dept. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Dept. 12 noon, Mr. Sinclair: Surgical Dyspepsia. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—11 A.M., Dr. McDougall: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

TUESDAY, Feb. 3rd.—4.30 P.M., Dr. L. R. Yealland: The Differential Diagnosis of Fits.

FRIDAY.—4.30 P.M., Mr. H. W. Carson: Prognosis in Breast Cancer.

Daily, In-patient and Out-patient Cliniques, Operations, Cliniques in Special Departments, &c.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: FEB.—MARCH, 1925.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Feb. 2nd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Epilepsy: Dr. Aldren Turner.

TUESDAY, Feb. 3rd.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Compression Paraplegia due to Tumours: Mr. Armour.

THURSDAY, Feb. 5th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., The Diagnostic Significance of Tremors: Dr. Risien Russell.

FRIDAY, Feb. 6th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Some Forms of Acute Encephalitis: Dr. James Collier.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.

THURSDAY, Feb. 5th.—12 noon, The Cerebro-spinal Fluid, Physiology and Pathology: Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

MONDAY, Feb. 2nd.—12 noon, Spinal Cord and Medulla: Dr. Hinds Howell.

The Fee for this Course will be £2 2s.

Dr. H. J. MacBride will give a COURSE OF EIGHT CLINICAL DEMONSTRATIONS, chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM, in the Wards at 10 A.M. on Tuesdays and Fridays, if sufficient entries are received. The Fee for this Course will be £2 2s.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.

WEDNESDAY, Feb. 4th.—3.30 P.M., The Optic Nerve: Mr. Leslie Paton.

Applications for this Course should be made early. Fee, £5 5s., if taken as a separate Course, or £3 3s. if taken with the General Course.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course. J. G. GREENFIELD, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 5th.—4 P.M., Dr. Paterson: Acidosis and Vomiting in Infancy and Childhood.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL POST-GRADUATE LECTURES, Marylebone-road, N.W.

THURSDAY, Feb. 5th.—5 P.M., Dr. C. H. Roberts: Malpresentations.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Feb. 3rd.—5 P.M., Dr. Graham Little, M.P.: Lichen Planus.

THURSDAY, Feb. 5th.—5 P.M., Dr. J. L. Bunch: Pruritus. Prurigo. Lichenification.

ANCOATS HOSPITAL, MANCHESTER.

THURSDAY, Feb. 5th.—4.30 P.M., Mr. Diggle: Diseases of the Oesophagus.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE (at Whitworth-street West Branch)

FRIDAY, Feb. 6th.—4.30 P.M., Dr. J. F. Ward: Management of Premature Infants.

MANCHESTER MEDICAL SOCIETY.

WEDNESDAY, Feb. 4th.—4.30 P.M., President's Address: Twins in Health and Disease.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES.

MONDAY, Feb. 2nd.—(At the Children's Hospital.) Dr. Fordyce: Clinical.

TUESDAY.—(At the Southern Hospital.) Mr. T. R. W. Armour: Fractures in the Neighbourhood of the Ankle-joint.

WEDNESDAY.—(At the Northern Hospital.) Mr. Simpson: Surgical Cases.

THURSDAY.—(At the Stanley Hospital.) Dr. Gullan: Pernicious and Other Anæmias.

FRIDAY.—(At the Royal Infirmary.) Mr. Jeans: Urinary Cases.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

TUESDAY, Feb. 3rd.—4 P.M., Dr. J. Thomson: Albuminuria in Children and Adolescents. Discussion to be opened by Dr. Rowand and Dr. Paton.

THE PEOPLE'S LEAGUE OF HEALTH.

Lectures on What We Should Eat and Why, at the Medical Society of London, 11, Chandos-street, W.

WEDNESDAY, Feb. 4th.—6 P.M., Lieut.-Col. R. McCarrison, I.M.S.: Food of Mankind Treated Historically and Geographically.

Appointments.

MILLER, C. H., M.D. Camb., F.R.C.P. Lond., has been appointed Assistant Physician to the Royal Devon and Exeter Hospital.

POWELL, A. T. W., M.B., B.S. Lond., Assistant County Medical Officer of Health for the County of West Suffolk.

ROSE, W. G., F.R.C.S. Eng., M.B., B.S. Lond., Assistant Honorary Surgeon to the Derbyshire Royal Infirmary.

TODD, ALAN H., M.S., B.Sc. Lond., F.R.C.S. Eng., Honorary Orthopaedic Surgeon to Croydon General Hospital.

Certifying Surgeons under the Factory and Workshop Acts: BROOME, F. C. S., M.B., B.S. Lond. (Ryde, I.O.W.); PARKER, C. S., M.R.C.S., L.R.C.P. Lond. (Coalville, Leicester); ALLAN, G. G., M.B., Ch.B. Edin. (Ayton); McCracken, W. J., M.B., B.Ch. Belf. (Haworth).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen University.—Second Asst. in Pathology. £250.
Bath, Eastern Dispensary.—Res. M.O. £150.
Bolingbroke Hospital, Wandsworth Common, S.W.—Res. M.O. (male) £200. Also H.S. (male) at rate of £120.
Brighton, Royal Sussex County Hospital.—H.P. £150.
Bristol, Cosham Memorial Hospital, Kingswood.—Res. M.O. £150.
Cardiff City.—Asst. M.O. £600.
Devizes, Wilts County Mental Hospital.—Asst. M.O. £350.
Finchley Urban District.—M.O.H. and Sch. M.O. £900.
Hastings, Royal East Sussex Hospital.—Hon. Radiologist.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.
Ladynell Sanatorium, Pendleton.—Asst. R.M.O. £350.
Lanark County.—M.O.H. £1300.
London Temperance Hospital, Hampstead-road, N.W.—Anaesthetist.
Maidstone, Kent County Ophthalmic Hospital.—H.S. £300.
Manchester, Ancoats Hospital.—Two H.S.'s. First 6 months at £100. Second 6 months at £150.
Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—H.S.'s at rate of £200.
Ministry of Pensions, Birmingham, Highbury Hospital.—Jun. M.O. £350.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. Cas. H.S. at rate of £100.
Rochdale Infirmary.—Radiologist.
Royal Chest Hospital, City-road, E.C.—Phys. Also M.O. in charge of Tuberculosis Dispensary. £750.
Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.
Ryde, Royal Isle of Wight County Hospital.—Res. H.S. at rate of £180.
St. Mark's Hospital for Cancer, Fistula, &c., City-road, E.C.—H.S. £200.
St. Pancras Metropolitan Borough.—Asst. M.O. £600.
St. Paul's Hospital for Skin and Genito-Urinary Diseases, Endell-street, Holborn, W.C.—Hon. S. and Hon. Asst. S.
Salford Infectious Diseases Hospital, Ladynell Sanatorium, Pendleton.—Asst. R.M.O. £350.
Salford Royal Hospital.—Surg. Reg. £100.
Salisbury, General Infirmary.—H.S. £150.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. at rate of £100.
Seamen's Hospital Society, Dreadnought Hospital, Greenwich.—Physicians.
Seamen's Hospital Society, Hospital for Tropical Diseases Endsleigh Gardens, N.W.—Med. Supt. £250.
Stirling District Mental Hospital, Larbert.—Second Asst. M.O. £275.
Stoke-on-Trent, North Staffordshire Infirmary.—H.S. £150.
West End Hospital for Nervous Diseases.—Asst. P., P. for Skin Dept., H.P. for In-patients. £150. Also Clin. Asst. in Special Dept.
West London Hospital, Hammersmith-road, W.—Hon. Surg. Reg. £100.
Woolwich Metropolitan Borough.—Asst. M.O. £600.
The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Ossett, Yorks, West Riding; and Bruton, Somerset.

Births, Marriages, and Deaths.

BIRTHS.

ALEXANDER.—On Jan. 18th, at Woodside, Plymouth, the wife of Captain R. H. Alexander, M.C., R.A.M.C., of a son.
BLACKWELL.—On Jan. 17th, at Maison Bruges, Don-road, Jersey, the wife of Dr. A. S. Blackwell, of a son.
CROSBIE.—On Jan. 15th, at Ardcaien, Londonderry, the wife of Dr. Douglas E. Crossbie, Clarendon-terrace, Londonderry, of a daughter.
QUIRKE.—On Jan. 22nd, at York-road, Edgbaston, the wife of Major M. J. Quirke, I.M.S. (retired), of a daughter.

DEATHS.

BARWISE.—On Jan. 24th, suddenly, at Derby, Sidney Barwise, M.D., B.Sc., D.P.H., Medical Officer for the County of Derby, aged 62.
BEST.—On Jan. 23rd, at The Firs, Waltham Cross, after three weeks' illness, Frederick Henry de Graves Best, M.R.C.S., L.R.C.P., in his 56th year.
IRVINE.—On Jan. 20th, at Wellington College, Berks, from illness contracted on war service, Arthur Gerard Cheyne Irvine, M.R.C.S., L.R.C.P., Captain, R.A.M.C., late of Selly Oak, Birmingham, aged 60.
MACKENZIE.—On Jan. 26th, at Albert Hall Mansions, Kensington, London, Sir James Mackenzie, M.D., F.R.C.P., LL.D., F.R.S., honorary physician to His Majesty in Scotland, aged 71.
POLLARD.—On Jan. 20th, suddenly, George Frederick Pollard, M.D., M.R.C.S., of 24, Uxbridge-road, Hanwell, aged 70 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE TREATMENT OF FRACTURES.

*A Post-Graduate Lecture to the Fellowship of Medicine,
delivered on Jan. 20th, 1925.*

By SIR W. ARBUTHNOT LANE, BART., C.B., M.S.,
PRESIDENT OF THE POST-GRADUATE MEDICAL ASSOCIATION.

I PROPOSE to consider the changes that have taken place in the method of treatment of simple fractures since I started operating on them in 1894, a period of more than 30 years. At that time the treatment of simple fractures was a disgrace to surgery. While that statement might be somewhat modified, I believe that at the present time no branch of surgery is as unsatisfactory as this is, and that a large proportion of the bad results of treatment are due in part to ignorance and in part to a want of skill of those into whose hands they are unfortunate enough to fall.

The average student while in the wards sees only a small number of cases of fracture, and he soon discovers that the views held and the methods and the results of treatment adopted by his several surgical teachers vary within very wide limits. The excellent radiography done at the big London or other large general hospitals enables him, however, to recognise the character of the fractures, and he must form his own opinion on the relative advantages of the several methods of treatment which he sees adopted. When he goes into practice he rarely has a case of fracture under his care and he soon realises the anxiety and risk that its treatment involves him in. He may experience great trouble in the accurate diagnosis of a fracture, since it is often impossible owing to difficulties of transport to obtain a radiogram in the case of fracture of the leg, and many of the radiographers and apparatus in country districts are not infrequently unable to produce perfect radiograms. A poor radiogram is often more misleading than none at all. The bad results of treatment, both functional and aesthetic, are very obvious, and as excellent radiograms can subsequently be easily obtained by the patient they may readily bring the medical attendant into a court of law and may expose him to great financial loss and professional discredit. It is not generally recognised how many actions for damages are stopped by the tactful advice of the consultant or by a compromise of a financial nature.

The most important law I ever formulated is that "the skeleton represents the crystallisation of lines of force." It is upon the knowledge of this law that the scientific treatment of fractures depends. The same law applies with equal truth to every soft structure in the body, and perhaps more effectually and obviously to the several portions of the gastro-intestinal tract, so as to impose on the community almost all the diseases of civilisation. Few surgeons appear to have sufficient mechanical knowledge and skill to deal effectually with fractures by operative procedures. As the risk of a possible unsuccessful result is so manifest, it is very advisable that any medical man who is asked to treat a fracture should call another into consultation, and he might with advantage choose an opponent. In this way he will materially safeguard his interests. In any case he should join a medical defence society when he starts in practice.

Operative Treatment.

In operations on simple fractures the operator may experience great difficulty in bringing the fragments into accurate continuity, especially when two bones are involved, or when there is much comminution. Even when the fragments are placed in apposition too short a plate may be employed with an insufficient number of screws, or the plate may be placed in an unsuitable position, or the precautions taken may not be sufficient to ensure perfect asepsis. It is no longer necessary to urge the wisdom of operating on simple fractures when the conditions which I put forward in my paper¹ in 1894 exist, the chief of which is the necessity of restoring perfect continuity of the fragments of a broken bone or bones by operation when it is of vital importance to the individual that the normal function of the skeleton has to be restored, assuming that it is not possible to obtain this result if other means have proved ineffectual. This applies to the leg even more than it does to the other bones, since it has to transmit the weight of the rest of the body.

The somewhat abrupt change in the manner in which the operative treatment of simple fractures was regarded by the profession was due to the wise action of the British Medical

Association on the initiative of Sir Victor Horsley, the then President of the Surgical Section, in appointing and generously financing a committee to investigate the result of the various methods of treatment and in printing their full report as a separate publication. It was entitled the Report of the Committee on the Treatment of Simple Fractures. It contained a very full and accurate description of the methods and results of the treatment of fractures in the several parts of the world. The committee comprised 16 members, who took part in the investigation on which they expended much time and trouble. The conclusions which they arrived at fully bore out the accuracy of my views. The committee was appointed in February, 1911, and the report was published in November, 1912. This is, I believe, the only occasion on which the British Medical Association has taken such thorough and effectual measures to arrive at the truth and to inform the medical profession on a subject which had long been discussed with so much violence and acrimony.

The change in the attitude of surgeons to operative measures was at first followed by disastrous results, especially in America, where fractures were operated on by a large number of medical men whose experience and skill varied within wide limits. The failures that resulted from such indiscriminate operations were due to insufficient aseptic precautions as well as to lack of mechanical knowledge. This brought about a reaction against operation, the procedure being held responsible and not the want of familiarity of the operators with the details necessary to ensure success. Many surgeons, hoping to obtain better results, attempted to improve on the simple methods which I employed, and which I have used with uninterrupted success since. They made more complicated steel plates or they used plates made of bone; they devised elaborate and intricate screws and screw-drivers, drills, forceps for grasping the fragments and retaining them in apposition, and many other modifications, all of which rendered more difficult a procedure which in principle is perfectly simple, but which may be made most difficult and unnecessarily complex in its application.

Lessons of the War.

The war produced a great change in the treatment of fractures by operation. Many of those surgeons who had been most actively opposed to operations on simple fractures did not hesitate to put plates and screws into the fragments of the broken bones in compound fractures usually produced by projectiles with the most disastrous results. It took quite a long time before the folly of this procedure was realised and a stop was put to this practice. Even when the wound had healed or was apparently quiescent, the introduction of such large foreign bodies as plates and screws not infrequently resulted in the renewed activity in the growth of septic organisms which had lain dormant in the bone and in the soft parts, so that disaster followed such operative procedures only too frequently. It took a long time before this complication was recognised and dealt with, but finally the results obtained with suitable precautions were excellent.

With all this experience some surgeons still continue to secure the fragments of bone in recent compound fractures by means of plates and screws with the same most unfortunate results. Every new procedure would appear to involve necessarily much damage and loss of life to the community, till the principles of the treatment and their application have been thoroughly grasped by surgeons generally. The use of steel screws has been objected to on the ground that they produce a rarefying osteitis, and that they have to be removed in consequence. This is due to imperfect asepsis and results only when the aseptic precautions employed by surgeons are insufficient. That this does not occur if enough care is taken is demonstrated by a large number of radiograms which I will show you. It is perhaps not sufficiently recognised that the moderate degree of asepsis which is employed in operations generally throughout the body is quite inadequate for procedures involving the burying in the tissues of a quantity of metal. This only too readily affords a nidus and a medium for the growth of organisms, which do not exist in the wound in sufficient quantity to produce trouble without the presence of the foreign body.

Great advances were made during and since the war in the treatment of severe compound fractures of long bones especially, and much was done in improving methods of traction in simple fractures, by which the resistance offered to the apposition of fragments by the shortening up of the soft parts by hæmorrhage and inflammation can be gradually overcome.

Treatment by Extension.

The most effectual method of treatment of simple fractures of the shafts of the long bones of the leg in which operative interference is not called for is by forcible extension usually under an anæsthetic followed by the use of an ambulatory splint. The splint must be so constructed that while the fragments are being constantly extended the patient is able

¹ A Method of Treating Oblique Fractures of the Tibia and Fibula more Efficient than those in Common Use, Transactions of the Clinical Society, 1893-94.

to lead an active life, moving the joints of the damaged limb with perfect freedom. In this way not only does the patient avoid stiffness of the joints and muscles which accompanies the ordinary methods of treatment, but the formation of callus is hastened by the free circulation of blood through the limb. This splint can also be employed with great advantage after the fragments have been secured by means of plates and screws. In the case of fracture of the shaft of the long bones of the leg this principle is carried out in an ideal manner by the extension apparatus devised by Mr. Hoefftke with which you are all probably familiar. The principle involved of replacement of fragments by extension, the continued exercise of traction by some form of apparatus, and the free spontaneous functioning of the muscles, soft parts, and joints in the vicinity of the fracture is that which governs the treatment of all simple and compound fractures. How often does one see a patient incapacitated for months, and sometimes permanently, by the limited range of movement of the joints in the vicinity of a fracture due to their having been left in one position for a long period. This complication is perhaps most serious in the case of a knee which has been allowed to become fixed in a flexed position.

In such cases of simple fracture in which the necessity for perfect function is not met by accurate apposition of fragments operation is called for. In the case of malunion following compound fractures only when the operator has every reason to suppose that the tissues have become freed from the presence of any organisms which existed in the original wound should surgical measures be undertaken with the object of restoring axial continuity of fragments. Such operations are often most difficult and may make a great demand on the knowledge, judgment, and skill of the operator. This is particularly the case when both bones of the forearm or leg are involved. Grafts of bones should be used freely to fill up any gaps that may remain between the fragments, though it should be borne in mind that quite a considerable interval can be readily filled in by the crystallisation of bone along the line of force. Great pains should be taken to secure them in position and immobilise them. The great advantage gained by the skilful employment of bone-grafts is illustrated by the remarkable work which was done by Mr. Gillies and the other surgeons and dentists at the Queen's Hospital, Sidcup. The methods devised and adopted by those men form a new era in the treatment not only of the damage produced by projectiles, but also of the various deformities and fractures of the bones of the face in civil life. The published works of Gillies and Pickerill contain full descriptions and illustrations of the various operative procedures requisite for these conditions.

CHARGES OF ADULTERATING MILK.

A CASE is to be stated by a bench of county justices in which a summons for selling milk deficient in cream was brought against a farmer and dismissed. A deficiency of milk-fat was apparently admitted, and also that there had been no deliberate abstraction of cream, the deficiency arising through the sample of milk upon which the proceedings were based having been drawn from the bottom of a vessel containing the milk, which had stood for a long enough time for the cream, or much of it, to have risen to the top. It was contended for the prosecution that this was tantamount to an abstraction of the cream and was to the prejudice of the customer. Whatever may be the decision of the divisional court upon this subject, it will tend to show whether legislation is necessary to safeguard the quality of milk supplied by dealers to the public or by farmers to dealers. It certainly is desirable in the interest of the public that no absolute defence should be possible when milk not up to a fixed standard is sold for food. Defences now raised, such as that the milk was as it came from the cow, neither skimmed nor adulterated, or was supplied under a warranty of quality would be better accepted in mitigation of a penalty than as a means of escaping all responsibility on the part of the person who sells to the consumer.

GEOGRAPHY AND CIVILISATION.

In a little book first published in 1915, revised and enlarged recently, Mr. James Fairgrieve¹ has endeavoured to trace the influence of geographical factors on the course of history—on the one hand by stimulating action, on the other by showing how and where the most effective action shall take place. The book deals with the material side of history, and frankly ignores "those spiritual aspects of the drama which do not exhibit the geographical control." Civilisation first dawned on the flood-plains of Egypt and Mesopotamia

¹ Geography and World Power. Fifth Impression. By James Fairgrieve, M.A., F.R.G.S. University of London Press. 1924. Pp. 373. 5s.

because here were protected lands, having abundance of water and warmth. Mr. Fairgrieve passes on to discuss the rise of civilisation in the Eastern Mediterranean, and the redistribution of world power after the break-up of the Roman Empire. The ocean and the forest are shown to be the factors which have shaped the development of Western and Eastern Europe. Other great physical features are discussed in dealing with the rest of the world, the central theme of the book—man's increasing ability to control energy—being maintained throughout. The last chapter is a fascinating study of probable lines of advance in the light of man's accumulated knowledge and experience. No sphere shows greater triumphs than that of medicine. The construction of the Panama Canal was rendered possible by the investigation of tropical diseases. Malaria cost the Suez Canal 38,200 francs in 1903, while in 1908 the cost was less than half that amount. Additional supplies of energy thus liberated must inevitably bring about changes in the distribution of mankind and in habits of life which will profoundly influence the course of history.

The book displays a fine sense of proportion in dealing with so vast a topic.

INTOLERANCE TO A DENTURE.

To the Editor of THE LANCET.

SIR,—In reply to the letter from "Medico" in your issue of Jan. 10th, I should advise him to regard his inability to wear a denture as due to psychological causes. I am taking for granted that the denture itself is all that it should be. Various gargles may be tried, but in a bad case success will only be achieved by practice and the will to overcome the difficulty.

I am, Sir, yours faithfully,

L. ERIC CHAS. PECKOVER,
L.D.S., R.C.S. Eng.

Worthing, Jan. 21st, 1925.

RED-HAIRED ALBINOS.

To the Editor of THE LANCET.

SIR,—The presence of red hair in persons with albinotic characters is an association which has been noted in a relatively small number of cases. Two children were recently shown at the Royal Society of Medicine with these features, and there are a few other references in the literature on the subject.

It will be of interest, therefore, to record the following observation made by the late Mr. Joseph Conrad, the famous novelist, which occurs in his unpublished diary under date July 4th, 1890, while camped about a week up country from Matadi on his way to the Congo—a journey which produced his celebrated story "Heart of Darkness." I am indebted to Mr. Richard Curle, Conrad's friend and executor, for this observation and for permission to publish the extract from the diary, which runs as follows:—

"In the evening, three women, of whom one albino, passed our camp; horrid chalky white with pink blotches, red eyes, red hair, features very negroid and ugly."

Here we have in a few words from the pen of a keen observer and a master of descriptive writing, a woman with complete albinism of skin and eye since she was chalky white with the erythematous blotches produced by sun-burn, and had a red reflex from the eye, but with red hair. Conrad notices the repulsive appearance which all albino negroes present to us, and the fact that negroid facial characters appear more marked in a white-skinned native.

I am, Sir, yours faithfully,

London, Jan. 21st, 1925.

HUGH S. STANNUS.

ON Jan. 21st the death took place at Hatch End of Mr. E. J. Sowerby, chairman of Messrs. H. K. Lewis and Co., Ltd. Owing to failing health he retired from active work in April last. He came to Gower-street in 1872, when Mr. H. K. Lewis was still at the head of the business. From 1880 he was manager under Mr. Morris Lewis. In 1905 a partnership was formed, of which he was the senior member. In 1915 the present company was created, Mr. Sowerby being chairman, with the other partners as directors.

A Plea

FOR

ACCURACY IN THERAPEUTIC DEDUCTION.

Being an Address delivered before the Medico-Chirurgical Society of Nottingham on Jan. 7th, 1925,

By EDWIN BRAMWELL, M.D. EDIN.,
F.R.C.P. LOND. & EDIN.,

MONCRIEFF-ARNOTT PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY, AND PHYSICIAN TO THE ROYAL INFIRMARY, EDINBURGH.

THE science of medicine has admittedly made great strides of recent years. Information as to the processes and causation of disease is steadily accumulating, the art of diagnosis is being constantly facilitated by the introduction of scientific methods of precision, brilliant results are being achieved in the field of preventive medicine, and the pharmacologist is ever adding to our store of knowledge as to the mode of action of the remedies we employ. While this is so it will be generally admitted that the progress of practical therapeutics has been in no way commensurate with the advance in our knowledge of the aetiology, pathology, and diagnosis of disease. I propose to discuss the reasons responsible for this state of affairs and the possibilities of their correction.

THE CLINICIAN RESPONSIBLE FOR THE EVALUATION OF TREATMENT.

The ultimate proof of the value of any remedy can only be established at the bedside. This is a fact which we are too apt to forget. Hypothetical considerations and the results obtained by the laboratory worker are invaluable because of the possibilities and indications they suggest, but the clinician is responsible for the final evidence. We clinicians are, however, in relation to questions of treatment, too often influenced by impressions or by expressions of opinion without analysing the reasons upon which our conclusions are based. Sir James Mackenzie, writing of medical progress, says with truth:—

"If the most enlightened members of our profession were to inquire into the grounds of their beliefs, even those most dearly cherished, how often would they be surprised to find on what fallacies their beliefs are based . . . the tendency to believe without reason is ever recurring, while the reverence for authority makes us accept statements without proof."

Those of you who have read Sir William Osler's delightful essay on Harvey will recall the lines he quotes which occurred to Henry Sidgwick in his sleep:—

"We think so because all other people think so;
Or because—or because—after all we do think so;
Or because we were told so and think we must think so;
Or because we once thought so, and think we still think so;
Or because having thought so we think we will think so."

Elsewhere Sir William Osler wrote:—

"It is so much easier to believe than to doubt, for doubt connotes thinking and the expenditure of energy, and often the disruption of the *status quo*. And then we doctors have always been a simple trusting folk! Did we not believe Galen implicitly for 1500 years and Hippocrates for more than 2000? In the matter of treatment the placid faith of the believer, not the fighting faith of the aggressive doubter, has ever been our besetting sin."

Although the methods of medicine have become so much more scientific there is still much loose thinking and loose talking about treatment. In the interests of progress it is essential that we cultivate the habit of refraining from making assertions which have no true foundation and which may give rise to or perpetuate erroneous and consequently misleading impressions admittedly so difficult to eradicate.

5293

PSEUDO-SCIENTIFIC MEDICINE.

Pseudo-scientific medicine is, indeed, one of the curses of the present day, more especially since it appeals to and misleads the educated layman, for, as Oliver Wendell Holmes points out:—

"Exalted wisdom, immaculate honesty, and vast general acquirements are insufficient to prevent an individual from having the most primitive ideas upon subjects out of his line of thought."

We are too apt to forget that although there is reason for believing that a remedy may do good, we are not justified consequently in assuming that the remedy in question does good until actual proofs are forthcoming. There can be no doubt that the elegant brochures which we are constantly receiving do much to maintain this state of affairs. Here we find extracts from the writings, it may be of eminent scientists, utilised for the purpose of emphasising the indications for treatment which the advertised preparations have been especially designed to meet; yet when we come to look for the results effected by the preparations in question we seldom discover any reference to facts supporting the vendor's claims, unless perhaps unconvincing and misleading statements by anonymous doctors of medicine who have, no doubt, been well remunerated for their services. To quote, from one of the last articles written by Sir William Osler:—

"We owe a debt to the modern manufacturing pharmacist, who has given us pleasant and potent medicine in the place of nauseous and weak mixtures, . . . but even the best are not guiltless of exploiting on the profession the products of a pseudo-science. . . . The length to which organotherapy has extended beyond the legitimate use of certain preparations is a notorious illustration of the ease with which theoretical views place us in a false position. Because thyroid extract cures myxœdema and adrenalin has a powerful action, it has been taken almost for granted that the extract of every organ is a specific against the diseases that affect it. This forcing of a scientific position is most harmful, and I have known an investigator hesitate to publish results lest they should be misapplied in practice. The literature on the subject issued by reputable houses indicates, on the one hand, the pseudo-science upon which a business may be built up, and, on the other, the weak-minded state of the profession on whose credulity these firms trade. . . . For years the profession has been exploited in this way until the evil has become unbearable, and we need as active a crusade against pseudo-science in the profession as has been waged of late (in America?) against the use of quack medicine by the public."

The medical man who is in the habit of "trying" the latest preparation on the market is to be regarded with suspicion, for he does so too often, not with the purpose of attempting to prove the efficacy of the remedy in question, but either because he is unduly credulous or in order to impress his patients and create the belief that he is *au fait* with medical progress.

THE FALLACIES OF EXPERIENCE.

Perhaps some of you may repudiate my imputations and tell me that we know from our experience that the remedies, or many of the remedies, we are in the habit of using, are effective. Doubtless we are often right, but in these days such an answer is insufficient. An assertion unsupported by facts is in itself of uncertain value, since its worth is dependent upon the reliability and judgment of the individual who makes it. It is necessary that we analyse our reasons, for is it not the case that when we form an opinion from experience there must be facts or impressions which have determined our conclusions?

Let me give you an illustration of an every-day habit of thought which demonstrates the possibilities of what I may term an erroneous experience. I treat a patient, let us say, with a certain drug. The patient improves and it may be recovers from his illness. I make most careful observations at the time, and after critically considering the evidence come to the conclusion that, although the facts do not justify a dogmatic statement, there is good reason for believing that the remedy in question has probably—note the

F

word probably—been responsible for the betterment. Later I meet with other cases of a similar nature. I employ the same remedy, and although I have not considered the facts with the same precision that I did in the first case, I receive the impression and perhaps express the opinion, although, mark you, I have really no additional data which justify me in modifying my original conclusion, that the remedy is useful in cases of the kind. As years go by and my precise observations become hazy and tend to fade from memory I may go so far as to say that this is the drug to use in the treatment of the disease in question. Yet you will observe that my experience does not justify any such assertion. There is, indeed, a natural tendency in the human mind for the wish to be father of the thought. As that wise old physician John Gregory, at one time professor of medicine in Edinburgh, remarked 150 years ago in his "Lectures on the Duties and Qualifications of a Physician," "There is an experience which, however extensive, does not render a physician more sagacious because it is not attended with the necessary observation." In the interests of therapeutic advance it is indeed essential that we cultivate the habit of analysing our reasons and reviewing our experience.

CRITICISM NOT SYNONYMOUS WITH SCEPTICISM.— THE METHOD OF SYDENHAM.

But some of you may say, "If I develop such a critical attitude of mind my pharmacopœia will be so limited." Do not misunderstand me. Criticism and scepticism are not synonymous terms, and must not be confused. I do not for one moment intend to imply, far from it, that we should refrain from employing reputed remedies which there is reason to believe may meet what we believe to be necessary requirements and may do good although their efficacy is as yet unproven. All I ask is, that in the interests of progress we refrain from loose statements and develop our critical faculties in order that we may be in a position to realise and utilise our opportunities should they arise, and thereby perhaps contribute something to the advance of knowledge. The adoption of this attitude will, I venture to say, in no way impair our therapeutic results. Facts are required, and the question is how are these to be obtained.

We have just commemorated the tercentenary of Thomas Sydenham. As Sir Humphry Rolleston says:—

"Sydenham not only revived but put into practice the dictum that medicine depends on the observation of, not on hypotheses about, disease."

Dr. Arnold Chaplin writes of Sydenham:—

"He drove home the great truth that the solution of the problem of disease, its manifestations, and its cure must be sought at the bedside by means of observation and inquiry, and not by an appeal to theory and authority sanctified by time."

It is the method of Sydenham applied to treatment which is called for at the present day to advance our knowledge of practical therapeutics. A crusade on these lines would be a fitting tribute to the great master of clinical medicine and help to remove a slur which undoubtedly reflects upon the good name of medicine as a scientific profession.

DIFFICULTIES OF THERAPEUTIC DEDUCTION.

Does a reputed therapeutic agent actually do good? This is the point of essential importance to the clinician. I would class all reputed remedies in two groups: First, those which have been definitely proved by the clinician to be of value in the treatment of disease, and, secondly, those which we believe ought to do good and which may do good although we have no actual proof of their efficacy. Our aim as clinicians must be to attempt to prove the value of the remedies we employ—i.e., to adduce evidence which will enable us to transfer affirmed therapeutic agents from the second group to the first. Facts, I repeat, are what we require.

The difficulties of therapeutic deduction are great and the fallacies numerous. Bedside conclusions are, because of the question of control, much more difficult than are the problems which confront the laboratory worker, although Sir Berkeley Moynihan perhaps exaggerates the position, no doubt wittingly, when he asserts that the difficulties of laboratory research are mere "bumble puppy" as compared with those of clinical deduction. But if we admit that bedside observations are essential to the progress of practical therapeutics, is it not our duty to recognise our responsibilities and face them? If we cannot be certain, let us at least, in the interests of progress, be as certain as we can. Why not look at a question of treatment just as we are accustomed to regard a problem of diagnosis, and if dogmatism is unwarranted consider the data and express our conclusions in terms of probability and possibility?

It is often difficult or impossible to determine whether our remedies have actually done good and whether they are to be credited with any improvement which has occurred in the course of their administration. Our logical faculty is here afforded full scope, and, as an old friend recently said to me, it is perhaps unfortunate that the subject of logic is no longer insisted upon as a necessary preliminary to the study of medicine. I would in this connexion commend to your notice a little book, published in 1864, by Dr. A. W. Barclay, physician to St. George's Hospital, being an expansion of his Lumleian lectures, entitled "Medical Errors or Fallacies connected with the Application of the Inductive Method of Reasoning to the Science of Medicine." The author writes of treatment:—

"The great difficulty in tracing out the relation of cause and effect consists in the presence of an immense number of circumstances, many of which it is impossible to exclude, while all may contribute more or less to the production or at least the modification of the result."

Speaking of *induction* in relation to the effect of remedies upon the course of diseases, Dr. Barclay says:—

"Legitimate induction does not demand any lengthy series to prove its truthfulness; but while it assumes a certain familiarity on the part of the observer with the facts bearing on the subject, its distinctive character consists in the discovery of some law which will stand the test of experimental inquiry, and is found true for every case which comes under its operation. If the law fail in any case where the special circumstances to which it relates are present, we ought to be able to show that some higher law interfered with its operation, or else we must abandon the law, or at least hold it in suspense."

Again he remarks:—

"The number of instances required to frame an induction is, of course, different, just in proportion to the certainty of the progress of the disease without the administration of the special remedy, and the possibility of other causes exerting any influence over it; and also in proportion to the clearness of the evidence by which the causation is established, the quickness or the invariableness with which the effect follows. If, on the other hand, in a few well-marked examples free from complication, the remedy is administered to the full extent of producing its constitutional effects, without arresting the progress of the disease, we may be certain that the supposed law is a false assumption."

We are constantly confronted with what I may term the *post hoc* and *propter hoc* consideration. Some of you may have heard of a method of treatment which I understand was regarded until quite recently, if not at the present day, as an infallible cure for shingles by the Chinese physicians. The medical man likens the patches of vesicles to berries; he paints a representation of a plate upon the surrounding skin and the head of a bird with open beak beside the plate. The vesicles disappear; the berries, he says, have been eaten by the bird. While this is an extreme instance of the *propter hoc*, it serves to illustrate the natural tendency of the human mind to attribute improvement to the measures employed in the treatment of disease when it is often the *vis medicatrix nature* which deserves the credit.

Many diseases run an acute course which we know from experience terminates either in death or complete recovery. When the patient survives it is often impossible to decide whether or to what extent the remedial measures employed have assisted the *vis medicatrix naturæ* in determining the result.

There are some acute diseases in which the damage attributable to the pathological process is done within the first few hours or days or weeks of the illness, although after-effects, paralysis for instance, result. While in some of these cases there is a varying degree of gradual improvement and it may be complete recovery, in others there is no tendency to betterment. Under such circumstances it is very often impossible if there is improvement to express an opinion as to what extent, if any, our remedies have assisted the reparatory processes of Nature in effecting the result. Were I to question your reasons for believing, even those of you who have had a considerable experience of organic nervous diseases, that muscular relaxation, massage, and electrical stimulation are of value in the treatment of the flaccid palsies, I venture to think that there are few of you who would be able to give me an answer based upon personal observations which would convince an unbiased mind. Yet you have probably all met with cases of symmetrical paralysis due to a polyneuritis in which control observations are possible. Again, there are certain maladies which are characterised by a chronic progressive course, interrupted it may be by remissions or temporary betterments, dependent upon the nature of the pathological process. Here the clinician must analyse his data with the greatest care before he ventures to assert that the treatment he has employed has been responsible for any improvement which may have occurred.

In times of epidemic, therapeutic conclusions may be vitiated by a change in the type of the disease. Some years ago a discussion upon the treatment of influenza took place before a medical society soon after a serious outbreak of this affection, when the value of several separate remedies was affirmed by individual speakers. The probable explanation was instructive. In the earlier days of the epidemic the mortality, notably from pneumonia, had been high, but later the disease took on a milder form which laboratory observations indicated was probably to be explained by the disappearance of the streptococcus. The diminished mortality, which was attributed by the speakers to the remedies they happened to be using at the moment, was evidently to be accounted for by a change in the type of the disease. Statistics may indeed be quite misleading. Because a series of patients suffering from the same condition recover when treated with a certain remedy this is in itself no proof of the efficacy of the treatment.

THE MENTAL FACTOR.

The mental factor is a common source of fallacy which is difficult to eliminate in estimating the effect of the remedies we use. The potency of suggestion in influencing the patient's mental outlook and his subjective symptoms is indeed generally admitted. We are apt to forget that our every word and action may make an impression upon the patient; it is also to be remembered that individuals vary greatly in their degree of suggestibility. Hence, it is of essential importance that, in attempting to arrive at conclusions as to the effect of remedies, we remember the possibilities of suggestion and that we avoid making suggestions which may vitiate our conclusions. Needless to say, no reference should be made as to the manner in which a remedy is supposed to act. Vaccine and, I think I may also say, endocrine therapy are two of the most abused methods of treatment at the present day, since a pseudo-scientific explanation often advanced to explain the anticipated effect of the remedy appeals with especial force to the mind of the uninitiated. Do not misunderstand me. Vaccines and glandular products are, we know, sometimes invaluable, and in the future will no doubt

with increasing knowledge come to occupy a more and more prominent place in treatment. But the indiscriminate way in which these measures are sometimes used is no better than pure quackery unless it be excused on the plea of gross ignorance.

I have referred to what I think may be regarded as the two chief difficulties in arriving at therapeutic conclusions—those dependent upon the nature of the disease and upon the mental state respectively, but there are others of lesser importance. Needless to say, change in environment, rest, diet, and freedom from worry are all factors which may favour improvement. Then I may remind you that differences may be observed according to the mode and time of administration and quality of the remedy. Thus we know that certain remedies are more effective when given in solution than in tablet form, while it sometimes happens, although the standardisation of remedies has done much to exclude this fallacy, that the preparation we are employing is comparatively inert as compared with the same preparation obtained from another firm. The remarkable fact that a remedy when first introduced often proves more effective than it does in the hands of subsequent observers is no doubt in some instances, though not always, to be accounted for by the influence of suggestion.

RESPONSIBILITY OF THE CLINICAL TEACHER.

Those of us who are teachers of clinical medicine bear a great responsibility, for we have a dual aim in view. Our purpose should be not only to produce the capable practitioner but at the same time to encourage the spirit of progress in the future generation. We are indeed responsible for creating the critical attitude of mind which is necessary for the advance of practical therapeutics. To quote Sir William Broadbent:—

"The basis of all clinical facility is observation, that is to say, the intelligent and instructed employment of the senses to obtain the facts, and in close relation with observation is inference, the right interpretation of the facts of observation . . . a third faculty which is called into existence is discrimination, an analysis and classification of the facts and inferences with due recognition of their significance and relative importance."

The clinical teacher cannot attempt in the time at his disposal, even admitting that he has the knowledge and ability to do so, to give the undergraduate an exhaustive knowledge of the very varied features of disease. Our aim should be to educate his powers of accurate observation and judgment rather than to fill his mind with facts, to see to it that he acquires a knowledge of the methods we employ, to train him to think in terms of disease as met with in the living patient, to instil in him general principles, to show him how to deal with patients, to teach him accuracy of thought and expression, and last, but by no means least, to kindle his enthusiasm. Even at the present day we may recall with advantage the words of John Gregory:—

"Among the infinite variety of facts and theories with which the physician's mind has been filled in the course of a liberal education it is his business to make a judicious separation between those founded on Nature and experience and those which owe their birth to ignorance, fraud, or the capricious system of a heated and deluded imagination."

But I am speaking especially of treatment. We have here to remember that evidence to the effect that a therapeutic agent has been proved in the laboratory to have a certain action is apt to appeal much more forcibly to the mind of the tyro, who comes to the clinical teacher fresh from his physiological studies, than a statement to the effect that a remedy does good although we know not why. This is an attitude of mind which we are constantly called upon to combat. Sooner or later, however, the student comes to realise that "nothing shows more ignorance of Nature or more self-sufficiency than to reject facts because we cannot account for them" (John Gregory). In the interests of progress it is

incumbent on us to train our students to bring to bear the same faculties of exact observation and inference, the same critical attitude and the same accuracy of expression in relation to treatment that we insist upon in the discussion of a problem of diagnosis. The student must not only be asked his reasons for believing that a remedy is of value in the treatment of a given condition, but he must be constantly called upon for evidence which he himself may have met with in his limited experience; further, he must be asked to discuss the facts in the actual case under consideration and express in as exact terms as possible any justifiable conclusions which can be drawn as to the effects of the treatment which has been employed.

THE GENERAL PRACTITIONER AND THERAPEUTIC ADVANCE.

The very prevalent and unfortunate use of the word research as the equivalent of laboratory methods and laboratory results tends to belittle the importance of clinical observation and is undoubtedly responsible for the general impression that when the young graduate commences general practice he relinquishes for good all opportunity of furthering the advance of medicine. This misconception calls for correction. There are indeed possibilities for furthering advance which are open to the general practitioner, especially perhaps in relation to practical therapeutics, and it is the duty of the clinical teacher to indicate these possibilities to the student and arouse his interest in the field which lies before him. Sanderson, the great headmaster of Oundle, whose views upon the public school system of education have aroused such widespread interest, laid it down as one of his axioms that when a boy leaves school he should do so full of confidence in the realisation of his potential powers. This is an ideal which I think we clinicians should aim at and encourage in our teaching. The undergraduate must be given to understand that, as regards treatment, we require facts and that he has it in his power if he makes use of his opportunities to add something to the store of knowledge. Sir James Mackenzie has, perhaps, done more by his demonstrations of what may be accomplished by a general practitioner than by the most valued contributions with which he has enriched the literature of medicine. An isolated observation, if correctly observed, controlled, and recorded, may indeed be of real worth. I may here remind you of Sir Lauder Brunton's discovery, when still a house physician in the Edinburgh Royal Infirmary, of the value of nitrites in the treatment of angina pectoris. While examining a patient who was suffering from an attack of cardiac pain, Lauder Brunton noted that the blood pressure was unduly high; knowing that nitrites produce relaxation of the non-striated muscle, he gave the patient some nitrite of amyl during a subsequent attack, with the result that the pain was almost immediately relieved. All of us, no doubt, have occasional opportunities of arriving at important therapeutic conclusions, but too often we fail through want of knowledge or want of training to appreciate the significance of our observations. Some weeks ago I met a practitioner of wide knowledge and sound judgment. I asked him as to his personal experience of the value of a certain remedy. He told me that he had definitely made up his mind as to its value and that he had observed so many cases in which he was satisfied that a cure had thereby been effected. His statements were sufficient to convince me that his conclusions were almost certainly justified. I said to him, "If you were to report these cases with the evidence as you have narrated it to me you would, I believe, be making a valuable contribution to medical literature." His answer was, "Unfortunately, I have not kept a written record of the details, and, besides, my experience is no doubt a matter of common knowledge." This reply emphasises both the difficulty the busy practitioner has in taking records of his cases and our lack of knowledge of established facts. It is, no doubt, impossible and

unnecessary for the practitioner to take notes of all cases; but if he realises the value of therapeutic conclusions and has been trained to recognise the possible fallacies the hope that he may thereby be enabled to contribute something to the advancement of knowledge will give him an added interest in his work.

AN "ILLUSTRATED" CLINICAL PHARMACOPŒIA.

What clinical proof exists, if any, as to the effect of this or that remedy? What are the proved facts? This is a question which we must of necessity repeatedly ask ourselves. A reputed remedy, as is well known, may be widely employed at one time and sooner or later fall into disuse to be replaced by another which in turn shares the same fate. Yet when we come to ask ourselves for an explanation we must admit that the answer to the question is generally to be found in the fashion of the moment. The opportunity of proving beyond doubt the value of a remedy occurs but seldom and the experience of each one of us is necessarily limited. Consequently, I feel that an "illustrated" clinical pharmacopœia, by which I mean a catalogued collection of remedies of proved value accompanied by clinical observations illustrating the existing evidence as to the efficacy of the remedies in question, would be of great value. A publication of this kind, which would no doubt require to be based on *de novo* observations and edited and compiled by competent authorities, would, it seems to me, be most helpful in presenting the existing state of knowledge. Again, it would serve to stimulate our interest and enthusiasm and encourage us by indicating what has been done and the fallacies which require to be met, to utilise our critical faculties. In addition, it would, I think, prove the best corrective of those two extremes, credulity and therapeutic nihilism, which prepare the ground for the pseudo-science and the "cure-all" propaganda of the present day.

CONCLUSIONS.

I have entitled this address a Plea for Accuracy in Therapeutic Deduction, and I hope that I have made my position clear, for to quote a recent writer, "Language is in truth the devil. It is always in danger of expressing too much or too little or something different from what you mean." The purpose of my thesis has been to emphasise "the fundamental difference between belief and knowledge, conjecture and certainty." I have reminded you that we clinicians constitute the tribunal, so to speak, which adjudicates the value of remedies, and that great though the difficulties often are this does not excuse us from shirking our responsibilities and doing all we can to add to the store of established facts. I have further indicated that there is here, I believe, a field open to the general practitioner who has been taught to realise the possibilities and at the same time trained to appreciate the fallacies with which he is confronted.

So far as I can see, it is only by a much more general recognition of the necessity for correct thought and precise statement than at present exists that pseudo-science and quackery can be successfully combated, a matter so essential in the public interests.

THE LATE DR. AUBURN WILKINSON.—Auburn Wilkinson, M.D. Durh., of Tynemouth, died on Jan. 25th in his seventy-eighth year. A native of Wark, North Tyne, he qualified as M.R.C.S. in 1873, and as L.S.A. in 1874, later graduating as M.B. in the University of Durham in 1885, he proceeded to M.D. in 1888. He was in practice in Tynemouth for 55 years, and only relinquished active duty at the onset of his last illness about two months ago. Amongst public appointments which he held were those of surgeon to the police and honorary surgeon of the Tynemouth Infirmary. He was an honorary associate of the Order of St. John of Jerusalem and an honorary life member of the St. John Ambulance Association. He was one of the founders of the Tynemouth Volunteer Life Brigade, of which he was the honorary surgeon at the time of his death. His wife predeceased him, and he is survived by a son and a daughter, a second son having been killed in the war.

Clinical Lectures

ON

APPENDICITIS: ITS CAUSATION, DIAGNOSIS, AND TREATMENT.

Delivered at the Bristol Royal Infirmary

BY A. RENDLE SHORT, M.D., B.S., B.Sc. LOND.,
F.R.C.S. ENG.,

SURGEON TO THE BRISTOL ROYAL INFIRMARY; LECTURER ON
PHYSIOLOGY IN THE UNIVERSITY OF BRISTOL.

PART II.*

THE TREATMENT OF APPENDICITIS.

It might be imagined that appendicitis and operation follow one another as daylight follows dawn, and there is no more to be said. Nevertheless, the subject has points of interest which we shall select for discussion. The following questions come up for consideration:—

(i.) What arguments may we fairly lay before an intelligent patient or relative to induce him to consent to operation?

(ii.) Is it ever wise to postpone operation in acute appendicitis?

(iii.) Why do certain cases die, and how may this be avoided?

(iv.) How is the case to be handled which does not make good progress after operation?

(v.) Operative technique.

Arguments for Operation.

What arguments may we fairly lay before the patient or relatives to induce him to consent to operation? There are two circumstances under which it may be difficult to obtain consent; when the patient is already very ill, or when many days have passed without improvement the difficulty usually passes. But during the first 24 hours of the illness, or in what Edmund Owen used to call the "fool's paradise" stage, all our arguments may be needed.

Taking the first of these contingencies and trying to look at it from the patient's point of view (and some few older doctors will still side with him), we must admit that the symptoms do not look very alarming as yet, and a majority of cases of acute appendicitis, left to themselves, will get well. What the percentage will be is difficult to say; perhaps about 80 per cent. will recover. Then why not wait a few days and find out which way this particular case is going, and if necessary operate to-morrow or the day after? Now, every up-to-date member of the profession knows that in the early case, seen on the first or second day, this course is liable to be disastrous, but all do not know just how to argue the point.

Let us start by pointing out that about 2500 persons die every year in England and Wales of appendicitis. If these had all been operated on on the first day the number would have been far less. The general mortality of acute appendicitis in all classes of practice is, according to my records, about 6 per cent.; none of my patients operated on within 24 hours died, and it is safe to say that the general mortality under those circumstances would be well below 0.5 per cent. That is to say, by waiting beyond 24 hours, 2000 lives are annually thrown away. In 1905, when the policy of waiting till the patient was really ill before operating was in force, the death-rate in 1000 cases collected by Lett at the London Hospital was 17 per cent.

Second, let us point out that waiting during the first 72 hours of the disease allows the risks to mount up alarmingly. In my series the death-rate following operation on various days works out as shown in the table (only cases with a rise of temperature are included). For the sake of confirmation a table given

by Lett¹ from the figures of the London Hospital is also quoted. (Table VII.)

TABLE VII.—*Mortality after Operation on Different Days of the Attack.*

Day of attack.	Present series.			Lett's series.		
	Cases.	Died.	Mortality per cent.	Cases.	Died.	Mortality per cent.
First ..	39	0	0	162	2	1.2
Second ..	85	4	4.7	152	6	3.9
Third ..	95	8	8.4	115	10	8.7
Fourth ..	51	5	9.8	50	2	4.0
Fifth or later.	77	5	6.5	183	10	5.4

Table VII. shows that, striking an average and speaking in round figures, of every hundred cases seen, to wait from the first day to the second will throw away three or four lives, and waiting from the first to the third will sacrifice eight lives per 100 cases seen. The third and fourth are the dangerous days.

The third argument concerns the length of convalescence. Operation before perforation avoids nearly all the complications of appendicitis, and obviates the need for drainage. The wound will be healed and the patient able to get up in 12 to 14 days. If removal of the appendix is delayed till suppuration has occurred, various complications may arise, and the wound is quite likely to discharge for many weeks.

The fourth argument, and one which seldom fails to clinch the matter, relates to the possibility of recurrence. It may be taken as roughly correct to say that if a person has one attack of appendicitis, there is a 50 per cent. probability of a further attack, the date and severity of which are totally unforeseeable. After two attacks the probability of a third attack is about 80 per cent. Evidently, therefore, the probabilities are very great that there will have to be an operation one day; if so, why not obtain the present benefit of it? It should always be borne in mind that a child with appendicitis is generally worse than the symptoms would indicate, relatively to an adult.

The second class of cases in which it may be difficult to obtain consent to remove the appendix is in the so-called "fool's paradise" stage. There may be an unaccountable and purely temporary drop in the temperature, or, more deceptive still, the pain may suddenly cease for a while and the tenderness lessen on account of the bursting of the tensely distended appendix. How often we are told by a triumphant mother: "The little boy's temperature was 101° when you took it this morning, doctor, and now it is only 100°, so he must be better, mustn't he?" For instance, I well remember driving 25 miles to see a farmer in a very lonely part of Somerset; on arrival, there was temporary relief from perforation of the appendix, and in spite of all persuasion the old man refused to have anything done. When the car was just disappearing from sight he relented and sent after us, but we were gone beyond reach. Next day, by this time thoroughly ill, he had us fetched down again and the appendix was removed and the widespread peritonitis drained. He put up a good fight, but succumbed after ten days. It was a life thrown away.

A genuine improvement, justifying delay, may be distinguished from the "fool's paradise" stage, in that there is *improvement in all respects*. The pain, and the tenderness, and the pulse-rate, and the temperature, and the vomiting, are each and all definitely better. To trust to one or two of these signs by themselves is to court disaster.

When is it Wise to Wait?

Is it ever wise to postpone operation in acute appendicitis? The majority of surgeons in this country would probably answer in the negative, but we shall allow certain classes of cases. For this purpose some classification is necessary. We shall employ the classification given in Table VIII., which is in general use.

* Part I. appeared in THE LANCET last week.

TABLE VIII.—*Classification of Cases, with Mortality.*

Group.	No. of cases.
A. Non-perforated cases, with rise of temperature. Usually operated on on the first or second day	132 (2 died = 1.4 %).
B. Non-perforated afebrile cases (appendicular colic)	40 (0 died).
C. Perforated cases, local peritonitis, not walled off	129 (8 died = 6.5 %).
D. Walled-off abscess, usually after fifth day	52 (2 died = 4 %).
E. Widespread (so-called "general") peritonitis	38 (13 died = 33 %).

Now, for the reasons already given, there is, in ordinary, no doubt at all that cases in group A should have the appendix removed as quickly as possible, because only in this way can we be sure of averting the perils of perforation. And perforation may occur very early. There is at present under my care a young man whose appendix perforated within three hours of the first rise of temperature. Given intervention before perforation occurs, very few patients will die. In the above series one of the two deaths in this group was from subdiaphragmatic abscess, and the appendix had probably leaked although this was not recognised at operation; the other died from pneumonia seven weeks after recovery from the operation, and it is only to avoid the charge of "cooking" statistics that it is included. The rule may be laid down then that symptoms of appendicitis with a rise of temperature above 99° and of pulse above 90 demand immediate operation.

In the second group, labelled B, there is pain, perhaps some vomiting, tenderness, and a little guarding over the right iliac fossa, but no rise of pulse or temperature. The diagnosis may not be altogether certain. Here, whilst it is no doubt quite justifiable to operate, it is our practice to wait. It is exceedingly improbable that the patient will come to any harm so long as a careful watch is kept on the pulse and temperature, and the appendix removed if they show a rise. If, however, the pain and tenderness have not completely disappeared after a week, or if there is a second attack, we advise operation.

In group C the appendix has already perforated and the general rule has been that it ought to be removed at once. But here some questions arise for discussion. It may be very difficult to decide if the appendix has perforated. Of course, if there is a palpable lump, or if the widespread tenderness and rigidity indicate peritonitis, the conclusion is readily reached. The time factor helps; if the symptoms are well marked after the lapse of 48 hours, perforation has probably occurred. On the other hand, it is uncommon for matters to have progressed so far under 24 hours, though exceptions to this generalisation are often seen. So long as skin tenderness above Poupart's ligament can be elicited, the probabilities are that perforation has not yet taken place. In cases of doubt, immediate operation is the wise treatment.

When it is fairly clear that local peritonitis is already present, and the patient is in a toxic condition, there is room for difference of opinion as to the best course to follow. In the present series the procedure has been to open the abdomen and remove the appendix at once, and this is the advice that would be given by the great majority of British surgeons. But there is a good deal to be said for the line of treatment, common in America and generally followed of late years at the London Hospital, of seeking to postpone appendicectomy from the third and fourth days to a later stage. The patient is put in the Fowler position, given morphia and fomentations for pain, and nothing by mouth except water, so as to inhibit peristalsis as far as possible. The argument is that the death-rate is high when the operation is performed on the third or fourth day, but falls afterwards; by the end of ten days it is very low. If time can be afforded for the purpose, antibodies accumulate in the blood, the pus becomes shut off by adhesions, and the acute toxæmia passes off to some extent. On the other hand, we have argued that the cases in which this happy course is followed would have been the ones which

would have done well after a third or fourth day appendicectomy, and that the patients who are in real danger of a fatal issue will not settle down if the surgeon holds his hand at that period but go from bad to worse, and that a few of them may be saved by third or fourth day operating who would be lost by further postponement. The good figures obtained when the appendix is removed, or an abscess drained after a week, are due mainly to the inclusion of a common type of case in which the symptoms are mild from the first, and no doctor is sent for until there is an obvious abscess; these all do well.

However, the very recent statistics from the London Hospital are so favourable that we must be prepared to allow the possibility of the wisdom of delay in toxic cases. It is not easy to compare figures from two widely separated districts, as the death-rate from appendicitis depends much more on the readiness with which patients seek medical advice, and on the prompt action of the general practitioner, than on the skill of the surgeon.

When the attack is manifestly subsiding, everyone will agree that it is better to wait. We ought not, however, to use to ourselves the phrase "manifestly subsiding," unless there is a definite improvement in *all the signs*—pain, tenderness, temperature, pulse-rate, vomiting, &c. Otherwise we may be deceived by a "fool's paradise" stage. After the attack is over, by all means remove the appendix, but the interval makes the operation safer and freer from delays in healing. It takes about a fortnight for the peritoneum to regain sterility, and we should wait at least a week, and preferably a fortnight, but patients are apt to get impatient.

Group D may be quickly dismissed. Here, as in the classical case of King Edward VII., operation has been delayed for five days or longer, and there is a well-walled-off abscess, which can be felt and often seen as a definite rounded lump. The happy course taken by the disease may be due to a mild infection, or to a retrocaecal position of the appendix, or to the fortunate accident that it had omentum wrapped around it. Operation is necessary, or the abscess will spread, and may rupture into the bladder or in some other disastrous direction, but there is no absolute urgency to an hour or two. Question may arise as to whether it is wise in these cases to remove the appendix or merely to drain. The former operation may be very difficult. An experienced surgeon will very, very seldom leave the appendix; the occasional operator, if he is wise, will do so frequently. If the appendix is left, about 17 per cent. of the patients will have further trouble (Lett's 1905 statistics). This figure does not seem high enough to make a second operation necessary in ordinary circumstances until there is a further attack.

In group E, with evidence of widespread, so-called "general" peritonitis, we have thought that operation is urgently indicated, though there is bound to be a heavy mortality. Probably we have often tried to do too much. Even if the patient is desperately ill, it is worth while to drain the pelvis under a local anæsthetic, and I have saved cases by this, the only possible procedure. Possibly the new operation of draining the thoracic duct may help to reduce the risks in these very grave cases. At the London Hospital they advise waiting a few days in hopes of localisation in the pelvis.

Why do Certain Cases Die, and How May this be Prevented?

In the series here presented as the basis for our study there were five deaths in private practice and 20 in hospital practice. Of the five in private practice, four were operated on far away in the country at small hospitals or at a country house, and only one at a Bristol nursing-home, yet, of course, the great bulk of private operating is done at a nursing-home. Better ambulance transport to remove country cases before they get very ill is urgently needed. The four who died were all very ill. One developed measles

a day or two after the appendicectomy, a second refused operation at my first visit and sent again next day. Another collapsed unexpectedly during a spell of torrid heat in July. The one nursing-home case who died was a man of 74 who travelled for many hours by train after he had perforated. Of the hospital cases, four died within 48 hours of admission. In another case only a suprapubic drain under gas was possible. Three died of pneumonia, one, three, and seven weeks after operation. Subphrenic abscess accounted for another, and multiple residual pelvic abscess for two more. There was one death from a very unusual cause—secondary hæmorrhage from the deep epigastric artery a month after operation. All the rest were carried off by peritonitis or ileus.

TABLE IX.—*Causes of Death after Operation for Appendicitis.*

	Cases.
Died under 24 hours	3
Measles and peritonitis	1
Pneumonia	3
Heat collapse	1
Secondary hæmorrhage	1
Subphrenic abscess	1
Multiple residual abscesses	2
Peritonitis or ileus	13

Now, of the causes of death shown in Table IX., some are preventable and some cannot be controlled. Early operation before the appendix perforates eliminates nearly all. The practice of giving an aperient to a patient who may possibly have appendicitis loses many lives. The more carefully the operator swabs out the pelvis and the soiled areas the fewer cases of residual or subdiaphragmatic abscesses and of ileus will he have to lament. The technique of drainage will be referred to later. It may be that in the future we may be able to save more lives in neglected cases by opening the jejunum under novocaine in cases of ileus, and by lymphaticostomy for peritonitis.

Management of the Case which does not make Good Progress after Operation.

I shall not say more about the treatment of peritonitis or of ileus which follows well-known lines, except to mention the fact that physostigmine salicylate and pituitary given coincidentally are much more effectual than either given alone in the treatment of ileus. In really grave cases several days after operation, when all other measures have failed to get the bowels to act and the prospects look gloomy, I have had great success on many occasions with a rather drastic "triple attack." The method is to give two drops of croton oil, then four hours later a turpentine or alum enema, and whilst it is still in the bowel, an injection of pituitary. It very seldom fails, and is, I believe, life-saving.

When the temperature remains persistently high after removal of the appendix we may allow a week, unless, of course, there are signs of serious trouble, before becoming alarmed about it. At the end of a week, a routine search must be made for the cause. It will nearly always be one of the following:—

1. *Suppuration of the Abdominal Wall.*—The diagnosis and treatment are obvious.

2. *Pericæcal Abscess.*—This is due to inadequate drainage at the operation or premature removal of a drain, and ought not to occur. Diagnosis and treatment are obvious.

3. *Pelvic Abscess.*—Due to inadequate cleansing or lack of drainage. The abdomen will present no signs except some distension, but there may be a mucous discharge from the rectum. The condition is recognised by a rectal or vaginal examination. As soon as it is large enough to be fairly easy to find, open it.

4. *Subphrenic Abscess.*—Generally in these cases nothing is to be felt in the abdomen, but the liver dullness is raised two intercostal spaces at the base of the right lung, with absent breath-sounds. Confirm by a skiagram, which shows doming up of the diaphragm on that side. I prefer to open these abscesses by an incision in the mid-axillary line,

resecting an inch or two of the two lowest ribs met with, and entering the abdomen below the pleural reflection, between the liver and the diaphragm. This gives beautiful access, avoids all trouble with the pleural cavity, and allows dependent drainage.

5. *Other Residual Intra-abdominal Abscesses.*—These may occur anywhere, but except in the situations just mentioned are easily felt as tumid swellings; just above the pubes is a common place.

6. *Pneumonia, Empyema, Bronchitis.*—These need no discussion. If confusion arises between subphrenic abscess and empyema, the skiagram will decide; in the former case the upper level of shadow is domed upwards, in the latter case it is horizontal.

7. *Suppurative Pylephlebitis (Portal Pyæmia).*—In this very grave condition there will usually be rigors, and perhaps a little jaundice. The liver may be tender and swollen. Most of these patients die, but I saved one by opening and draining the abscess, which was fortunately solitary and superficial on the upper surface of the liver.

8. *B. coli Pyelitis.*—Once or twice I have seen a persistent temperature after appendicectomy due to this cause. The diagnosis is given by the exclusion of other causes, the presence of *B. coli* in the urine, and the rapid recovery after the administration of hexamine.

Operative Technique.

I shall deal with this very briefly.

(1) Use the Battle incision, not the McBurney. The idea that there are more incisional hernias after the former than when the muscle-splitting operation is performed is incorrect. If a drainage-tube is used through the incision any operation may be followed by a hernia; if the drainage is kept separate, I have only once seen an incisional hernia after the Battle operation. Its great advantage is the much better access without cutting across the oblique muscles. It is difficult to deal adequately with an infected pelvis through the McBurney incision unless its alleged advantage is sacrificed by cutting across muscle fibres. If there is a palpable swelling, make the incision partly off the swelling and partly over it. Try not to divide more than one intercostal nerve, or there will be some weakness of the rectus. Do not allow a nerve to be caught in a ligature. Even motor nerves contain sensory fibres.

(2) However difficult it may be to do so, the stump of the appendix must be securely buried or otherwise shut off from the peritoneal cavity. It is useless to trust to drainage to make good any deficiencies in this direction. The removal and secure closure of the appendix may be a very easy operation or it may be of exceeding difficulty.

(3) Thoroughly cleanse the pelvis and the perirenal pouch also if they are soiled.

(4) *Drainage.* If it is decided to drain (and if the appendix has perforated, in spite of the modern tendency to the contrary, it is probably safer to do so), close the incision and use stab-drains. Of late years I have given up drainage-tubes to a considerable extent in favour of corrugated rubber dam, which does not cause tissue-necrosis or exert any pressure. In a case with local and pelvic peritonitis the drainage-scheme is: (a) A long narrow strip of rubber dam, through a median stab just above the pubes, down to the bottom of the recto-vesical pouch; (b) a rubber tube, through a stab in the loin, just entering the peritoneal cavity close to the site of the appendicectomy; (c) a narrow strip of rubber dam at the lower end of the operation wound, entering the rectus sheath but not entering the peritoneal cavity, to control suppuration of the abdominal wall.

I have never known an incisional hernia follow this method of drainage. If it had been followed at that time, I do not think the death from secondary hæmorrhage from the deep epigastric artery would have occurred.

THE ACIDIC VALUE OF THE URINE IN SKIN AND OTHER MANIFESTATIONS.

A STUDY OF ABNORMAL HYDROGEN-ION CONCENTRATION AS AN INDICATION OF DISEASE.

By F. CARMINOW DOBLE, M.R.C.S. ENG.,

TEMPORARY CAPTAIN, R.A.M.C.; SPECIALIST IN DERMATOLOGY FOR THE LONDON DISTRICT; HONORARY CASUALTY OUT-PATIENT SURGEON, ST. PAUL'S HOSPITAL FOR SKIN AND GENITO-URINARY DISEASES, LONDON.

URINE with a high acidic value is a very much commoner condition than is generally supposed. Many people have it in a definitely pathological degree who are apparently in perfectly good health. It would appear that this state is an indication of some underlying disease, the nature of which we know nothing. This obscure condition is a grave menace to our well-being, and sooner or later, on the advent of some additional or superimposed strain, some organ or tissue of the body will refuse to function properly. It prevents or hinders the clearing up and healing of lesions and there seems to be no doubt that it can, by itself, poison various tissues of the body. I make the suggestion that it is usually congenital but may be acquired. Treatment with alkalis will relieve the patient and allow the lesions to heal up, but the high concentration of the hydrogen ions in the urine will return and the patient will have a relapse when another strain is put upon the organs or tissues. Thus it would seem that this high acidic value, apart from treatment, is permanent. The only exceptions that I have found so far to this rule are in cases of gastro-intestinal toxæmia. In this type of case there is usually an erythematous or papular rash and the pH value of the urine varies from 5 to 5.6. When the rash fades away, the pH value of the urine returns to normal, even without treatment, showing that the phase is only a temporary one.

Although I have been working on this state for the last 21 months, chiefly from the dermatological point of view, I have been struck by the number of patients in the medical wards who have shown a great intensity of the acid in their urine, and by the change for the better that takes place the moment they are treated with large doses of alkalis.

The pH Value of the Urine.

The only method employed throughout my investigations was to find out the pH value of the urine, as I found there was no increase in the actual amount of acid present in the urine of the patients I was testing. In other words, there was no true acidosis. If the pH value was pathological, I endeavoured to bring it to the normal limit and keep it there. This normal limit I have found by examining very large numbers of healthy men to be from 6.4 to 6.8. I was careful to exclude all those with skin diseases, especially seborrhœics. Even then I found a small percentage with a high pH value. It is analogous to those people who without any signs or history of syphilis are found to have a strongly positive Wassermann reaction. Also, as with them, the question arises, should they be treated? Until more is known as regards the causes of the state that question cannot be answered.

The cardinal fact underlying my clinical investigations is that the mean hydrogen-ion concentration of the urine in certain skin and other diseases is of a high order, but that no abnormal increase in titratable acids can be found associated therewith.

The possible causes of this might be: (1) The excretion of an abnormal acid of high dissociation constant. (2) The deficient excretion of one or more of the normal urinary buffers so that the normal urinary acids cause a marked increase in the hydrogen-ion concentration. (3) The abnormal excretion of

some element which causes increased dissociation or hydrolysis of one or other of the urinary constituents which are combinations of a weak base and strong acid and vice versa, or to some other cause.

The fact that quite moderate doses of alkalis are sufficient to change the pH value to normal limits instead of the massive doses required in true acidosis cases to cause the same pH change seems to indicate that there is no real acidosis underlying the condition, but that some equilibrium change or changes cause the normal urinary acids to give a high intensity value.

The pH value of the blood is of no help, but the clue to the urinary changes may possibly be found in the blood chemistry of these cases. In the quantitative blood examinations of the acid and alkali buffers, the alkali reserve, the pH values obtained from determinations of the free and fixed CO₂ ratio, and direct electrometric measurements might be of value in determining the operative factors. The changes in the sweat and saliva promise to be of interest.

Examination of the Urine.

By taking morning and evening specimens I found that the pH value varied within certain limits according to the amount and kind of food taken, and also with the interval of time since the last meal. It is better to start with a specimen taken the first thing in morning and the last thing at night, and later to examine 12-hour samples. Occasionally I find it useful to also test a specimen taken two hours after a big meal. The urine should be examined daily until the patient is well under treatment, when once or twice a week will suffice.

The Urine in Patients with Skin Manifestations.—In some 500 cases of patients suffering from skin diseases I found that all those with seborrhœa, seborrhœic eczema, acne, and cheilopompholyx, without a single exception, had a urine with a pH value of from 4.8 to 5.8, unless alkalis had been given. Infantile eczema is not a seborrhœic condition, the urine in these cases gives a normal pH value, and the patients do not improve on alkalis.

Dr. H. W. Barber, in an article written in conjunction with Dr. H. C. Semon entitled *Some New Observations on the Ætiology and Treatment of Seborrhœic Eruptions*,¹ was the first to point out that the seborrhœic state is really a manifestation of acidosis, and that in the great majority of cases the activity of the inflammatory processes ceases as soon as the urine is rendered virtually alkaline. The article goes on to say that although the chemical examination of the urine has never revealed the presence of di-acetic or β -oxybutyric acids, nor is it suggested that the degree of acidosis present in all resembles that commonly met with in diabetes, it is not to be denied that there are certain resemblances in the clinical features of the two diseases.

In the light of my recent work I am in absolute agreement with these views except that I consider that the word acidosis is not the correct word to use for this condition, and suggest that "acidic value" is more in accordance with chemical findings.

Dr. Richard L. Sutton, in his book, "Diseases of the Skin,"² writes as follows:—

"Barber and Semon believe that all patients with status seborrhœicus suffer from relative acidosis, and recommend the adoption of appropriate treatment, but Sweitzer and Michelson,³ in an exhaustive and careful series of studies, were unable to establish any etiologic relationship between the two conditions. Inquiry among pediatricians disclosed the fact that in a large number of cases of acidosis observed, due to a variety of causes, no cases of infantile eczema or of seborrhœic dermatitis were encountered."

These investigators must have fixed their attention on the amount of titratable acids and ignored the hydrogen-ion concentration altogether, otherwise they could not have failed to have been struck with the extraordinary high acidic value of the urine of all the seborrhœics they examined.

The Action of Alkalis on Patients with Skin Manifestations.

Seborrhœic Eczema.—The action of alkalis on patients with this condition is very marked, even on those cases who have had eruptions for years. The weeping stops, the angry look dies away, the redness becomes paler and paler, the irritation ceases, a thin bluish-coloured skin covers up the lesion, and then normal skin appears and the lesion is healed. This can occur without any local treatment of any kind having been applied. The length of time taken to effect a cure depends on how long it takes to bring the urine to a normal pH value, and this naturally varies with each case. If too much alkali is given and the pH value of the urine reaches from 7.2 to 8, the lesions tend to reappear, and unless the dose is cut down or stopped the patient's condition may become worse. This rather rare result of over-treatment is well illustrated in the following case:—

CASE 1.—J. P., a man, aged 36, who had had no previous skin trouble. He was badly wounded in 1916 and was given an injection of anti-tetanic serum and sent to hospital in England. Here he was given a second injection which, he states, caused him to break out in a rash all over his body which remained long after his wound had healed; in fact, he was in hospital for 18 months. In time his skin became normal except for a weeping dermatitis covering both his hands. He had received treatment from several eminent dermatologists without the lesions clearing up. He was forced to wear gloves continually, and consequently was too shy to dine away from home. He was very anxious, on his first visit to me, to attend a big dinner in Paris 48 hours later. I gave him half a pound of bicarbonate of soda with instructions to take a teaspoonful three or four times a day. His hands were perfectly healed by the time he arrived in Paris. Against my advice he continued taking large doses of this salt and in a few days, after consuming some pounds, he developed a weeping dermatitis covering practically the whole of his body. The pH value of his urine was then 8. On stopping the medicine the rash cleared up, taking ten days to do so.

The next case shows the action of alkalis both on the skin condition and on the kidneys.

CASE 2.—J. J. R., a man, aged 49, had had seborrhœic eczema for ten years, chiefly limited to the face and neck. The skin was red, swollen, and weeping. He stated that it started as a small itching spot on his nose which he scratched. He must have infected this with his nails, for the spot rapidly spread, and in a few weeks his whole face and neck was a mass of weeping and irritating eczema. Every form of local treatment was tried for years, but with only slight relief. He spent several hours a day either bathing his face with lotion or smearing ointment on it. He was unable to go into a heated room or to drive in an open car. At times it was impossible for him to shave, and he never was able to lather or wash his face with soap.

When first seen in April, 1923, the report on his urine was as follows: Sp. gr. 1010, very acid to litmus, H-ion concentration, pH 5.8, trace of albumin present, but no nucleoprotein, acetone, aceto-acetic acid, phosphates (earthy), urates, bile salts, or sugar. Quantitative albumin (Esbach) was under 0.01 per cent. Centrifuged deposit: Microscopical examination showed a few granular casts, a few tubular renal epithelial cells, and a few leucocytes, but no red blood corpuscles or crystals, &c.

Under drachm doses of sod. bicarb. his condition rapidly improved, and I was able to reduce the amount by half in a few weeks. He carried on the same local treatment that he had done for years. Not only did the eczema clear up, but his kidney condition, as shown by the examination of his urine, became normal. I noticed that if his urine stayed between 6.4 and 6.8 his face remained in a perfectly normal condition. If it went to 5.9, his skin started to inflame, and casts, renal cells, and leucocytes reappeared in his urine. If it went to the alkaline side of 7 his face condition remained good, but the casts, &c., reappeared. Thus the pathological report on his urine on Nov. 8th was as follows: Sp. gr. 1014, very alkaline to litmus, H-ion concentration, pH 7.6, albumin present and a trace of nucleoprotein.

The amount of albumin present was more than that found in all recent specimens, but was too small in amount for quantitative estimation. There was a trace of indican, but chemical tests showed the absence of blood and pus. There was no acetone, aceto-acetic acid, bile salts, or sugar, and no urates, but earthy phosphates were abundant. Centrifuged deposit: Microscopical examination showed

granular hyaline casts and a few renal cells, leucocytes, but no erythrocytes. Triple and stellar phosphates were present. The increased albumin, casts, &c., may possibly be due to the abnormally great alkalinity of the urine.

From December, 1923, to the present time he has a slight relapse of his skin condition when his urine is very acid, but his renal state remained very good, even when his urine reached 5.6 or 7.6. So it appears that the treatment has allowed his kidneys the chance of recovering. Thus on May 30th, 1924, the report on his urine was as follows: Sp. gr. 1016, alkaline to litmus, H-ion concentration, pH 7.6. There was no albumin, nucleoprotein, blood (chemical), indican, acetone, aceto-acetic acid, urates, bile salts, or sugar, but earthy phosphates were very abundant. Centrifuged deposit: Microscopical examination: No casts, renal cells, leucocytes, or other organised cells were present, but a few stellar phosphates, triple phosphate crystals, and a very large amount of amorphous phosphates. He is still taking bicarbonate of soda in half-drachm doses two or three times a day. He is leading a perfectly normal life, and except for meat he eats anything he likes.

CASE 3.—L. S., a nursing sister, had an outbreak of seborrhœic eczema in Malta three years previously. When I first saw her 15 months ago she had a very acute, weeping, and irritating dermatitis, involving chiefly her arms and legs. It took a pound and a half of cotton-wool a day to absorb the fluid from the lesions. I ordered her to bed and put her on medium doses of bicarbonate of soda and potassium citrate. I gave her no local treatment whatever. She begged to be allowed to apply one of the many lotions she had been in the habit of using and complained bitterly when this was refused. In two days the lesions were healing and had quite cleared up at the end of ten days. Since then I hear that she had a slight relapse when she had an attack of influenza some months later, but on continuing the medicine, which she called "the magic draught," it completely healed up.

The cases described above illustrate very well the action of alkalis on seborrhœic eczema; they are only three out of over one hundred examples I could quote. Rarely one meets cases that do not clear up easily under alkalis, even with the help of local treatment. These cases are due to a skin sensitisation to a staphylococcus, fresh lesions breaking every now and then at a distance from the original focus. This staphylococcus is usually *S. aureus*, sometimes *S. albus* or even *S. citreus*. These cases require to be desensitised by injections of autogenous vaccines, peptone injections, low carbohydrate dietary and other means. These have been described by Dr. Barber. Cheiropompholyx I place in the same category as the above, the action of alkalis is just as remarkable, and no local treatment is usually required.

Seborrhœa.—The action of alkalis on seborrhœa, wherever it is situated and whatever the type may be, is a very great aid to, but can never replace, local treatment.

Acne.—Here, again, local treatment must be energetically carried out. One case will serve to describe the change that takes place when alkalis are administered.

J. M., a girl, aged 17, had been treated for acne since she was 11. For the past three and a quarter years she had been under the direct care of a distinguished dermatologist. Every form of modern treatment had been tried in her case, including the administration of an autogenous vaccine and radiotherapy. When first seen by me her face and back were covered with typical acne. The pH value of the morning urine was 5, and the evening specimen 5.1. Three days after the administration of alkalis, when the pH value had been raised to 5.3, she started to improve. At the end of a week the change was very marked. What especially impressed her mother at this time was that the scalp and skin were no longer greasy and no fresh "spots" had appeared. At the end of a fortnight she was well on the way to recovery. I noticed that the deep-seated pustules had worked their way to the surface. In four weeks she was clear of active signs, and all that remained were a few healing scars and some small comedones.

Other Skin Conditions.—Amongst other skin conditions that have an abnormally high pH value and that greatly improve or are cured by administering alkalis are prickly heat, carbuncles, abscesses, boils, and a generalised prurigo. This latter condition is often seen in cases that have, to all intents and

purposes, a normal-looking skin. I find in these cases that before the itching is relieved the pH value of the urine has to be pushed up to 7.5 or 8.

The Urine and the Action of Alkalis in Other Diseases.

It is with diffidence that I write on the high pH value of the urine in other diseases than those of the skin, and it is really to suggest the lines that research workers might follow that I state my limited experiences. In gout and rheumatism the pH value is high and alkalis give marked relief. Neurologists might test out the acidic value in their cases. Epilepsy, neurasthenia, and hysteria are examples of diseases in which I have found a high percentage of abnormal acidic urines. It would be of great interest if independent observers would record their researches in the large group of psychic and other ailments of the central nervous system, many of them involving a derangement of the autonomic system, vago- and sympathicotonic, and which in many cases exhibit cutaneous manifestations. It would seem worth while if the pH value of the urine of all patients admitted to hospital was ascertained, as alkalis are of such remarkable value in diseases as far apart as blackwater fever and broncho-pneumonia. It may account for the benefit some people derive from taking proprietary salts, and attendance at alkaline spas.

I have recently examined the urine in the cases that have shown a marked reaction to vaccination, injections of T.A.B. vaccine and serums. They all show a pH value of from 5 to 5.6, even when they were well again. If alkalis are given to cases that have a high hydrogen-ion concentration to their urine, I find that when their urine is approaching the normal limit the patient generally volunteers the statement that any symptom of stiffness after exercise, headache or heavy feeling, previously complained of, has gone, and that he wakes up fresh in the morning, and getting up is no longer any trouble to him. Chronic dyspepsia is greatly relieved or has absolutely disappeared, also, in some instances, certain articles of diet which before caused inconvenience or even rashes or other toxic symptoms, can now be eaten with no bad after-effects. Strawberries and bananas are two instances.

Treatment with Alkalis.

In each case it is necessary to experiment before the exact dose can be gauged. Dr. Barber and Dr. Semon, in the article quoted above,¹ state how difficult it often is to bring the urine to the normal limit. Here my experience in the treatment of gonorrhoea was useful, especially that gained when I was experimenting with acriflavine, which has to be given with the patient's urine alkaline. The mixture which I now always start with, and which I call mist. acidosis (for want of a better name), is a modification of Dr. Langdon Brown's mixture for the treatment of the acidosis in diabetes. It consists of:—

R	Sod. bicarb.	..	..	gr. 30
	Pot. bicarb.	..	..	gr. 25
	Pot. cit.	..	..	gr. 20
	Tinct. card. co.	..	..	min. 30
	Aquam menth. pip.	..	..	ad oz. 1

This is given three times a day, between meals, increasing or decreasing the dose according to the pH value of the urine.

My best thanks are due to Dr. Barber for his advice and help, to Dr. Lyn Dimond for his interest in my work and for his skill in carrying out the pathological side of the investigations, and also to Major R. E. Todd, M.B., R.A.M.C., for many useful suggestions and his help and encouragement.

THE PREVENTION OF A HIGH MATERNAL MORTALITY FROM PUERPERAL SEPSIS.

By ETHEL CASSIE, M.D. EDIN.,
D.P.H. EDIN. & GLASG.,

CHIEF MEDICAL OFFICER FOR CHILD WELFARE, BIRMINGHAM.

MUCH attention has been directed recently to the fact that maternal mortality in childbirth remains almost unaffected by the general fall in the death-rate, and that the most important single factor in maintaining this high mortality is puerperal sepsis. In spite of the attention directed to the subject and its importance, a certain vagueness and lack of focus appear to prevail in the attitude adopted to the condition. There still seems to be considerable disagreement as to its nature, its evidence, and as to the methods of prevention.

The history of our knowledge of the condition has been retailed so frequently of late that no further recapitulation is required. It is unnecessary to go further than Dame Janet Campbell's recent report on Maternal Mortality, in which a brief and admirable historical summary is given. It is rather surprising, however, to find a little further in the report the statement "we have not as yet exact knowledge as to the causation of the infection." As long ago as 1910 Dr. A. W. W. Lea, in his valuable book "Puerperal Infection," set forth what is the accepted modern view, which simply considers puerperal sepsis as a wound infection, and therefore due to any organism capable of producing a septic infection. The variation in the organisms found is therefore what one would expect. Unfortunately, there still appears to be a widespread idea that puerperal sepsis must be a specific infection. This belief is, I believe, a mischievous one, since it affects the attitude of the attendants on the patient, and leads to mistakes in both preventive and curative methods. Considering the condition then as a wound infection, the points of interest are how far infection depends on the varying factors involved: on environment, on injury, on hæmatogenous infection, on insufficient drainage, and finally, how much it is influenced by the resistance of the patient. These are important points and have been much debated; it is possible, however, that there may be some interest in considering them afresh in the light of a special and close investigation carried out in every case of puerperal sepsis notified in Birmingham during a period of 12 months. The whole interest of the inquiry centred on the question of prevention, methods of treatment were noted, but their relative value was not contrasted.

It is first necessary to consider the position in Birmingham as regards the midwifery service. There are 196 certified midwives in practice, whose work is closely supervised by the public health authorities. These women undertake a large proportion of the midwifery. During 1922 they attended 13,128 women in childbirth, representing 66 per cent. of the total births in the city. The larger proportion of the remaining cases were attended by medical practitioners assisted by the midwives or handywomen. Unfortunately, a very large proportion of women are still permitted by the medical practitioners to engage these handywomen to assist actively at the confinement and in the nursing during the puerperium. In addition the maternity hospital dealt with 787 cases; these were either primiparae or cases where some abnormality was present or suspected, while a rather larger number were confined in the Poor-law hospitals, there being no restriction as to admission. There are several small maternity homes, including a municipal maternity home. Puerperal sepsis cases are treated at the Women's Hospital in a special ward. Cases are also treated in the Poor-law Hospitals. The patients in all three institutions are under the care of skilled obstetricians, and no case is refused admission. In consequence of this excellent provision for treatment

the number of puerperal sepsis cases notified in Birmingham per 1000 of the population is higher than in other cities—e.g., Leeds and Liverpool—where the only provision is a ward in the infectious disease hospital; while in Nottingham, where no special provision appears to have been made, the case incidence was at a minimum. The mortality per 1000 births from puerperal sepsis is a more reliable figure than the case-incidence, and in this Birmingham is below all the larger cities except Bristol. (Table I.)

TABLE I.

—	Case-incidence.	Mortality.
	Per 1000 of population.	Per 1000 births.
England and Wales ..	0.06	1.38
London ..	0.08	1.42
Birmingham ..	0.11	1.21
Manchester ..	0.23	1.94
Liverpool ..	0.07	1.83
Leeds ..	0.07	1.28
Sheffield ..	0.12	1.68
Bristol ..	0.08	0.60
Nottingham ..	0.03	1.30

The number of cases notified during the period of 12 months (October, 1921, to October, 1922) amounted to 129. Of these 129, 35 were abortions, and the remaining 94 pregnancies in which the period was over seven months. Of these 94, five were not cases of puerperal sepsis. These five were of some interest from the point of view of diagnosis and are given below: 1. Pyelitis (chronic). 2. Scarlet fever (previous case in house). 3. Mammary abscess (pyrexia on the fifteenth day). 4. Acute bronchitis. 5. Chronic nervous disease (probably disseminated sclerosis, though a final diagnosis was not made. It was taken for a cerebral embolus, with puerperal sepsis, owing to the incomplete history).

Incidence.

In 1922, 19,850 births were notified in Birmingham, and the number of cases of notified puerperal sepsis was 137; this gives a percentage of 0.69, which is, of course, a very low incidence, but may be taken as an average. Consideration of this figure raises the question, "What is the true incidence of puerperal sepsis?"

Obviously the notified cases give no real indication of the condition, since only the severe cases requiring hospital treatment, or those who cannot well be treated at home for other reasons, are notified. Some indication can be obtained from the number of midwives' cases in which medical help was called for pyrexia. This is not, of course, an absolute guide, but the figures are very suggestive as shown by subsequent inquiry. It should be noted that only a small proportion of these cases are included among the notified cases of puerperal sepsis. The midwives sent for medical help for rise of temperature alone in 111 cases during 1922.

In 30 of the midwives' cases investigated in this inquiry medical help was called for during the puerperium; this may be taken as an average figure, for though the period does not absolutely coincide it is near enough for the purpose. It may then be taken that roughly two-thirds of the cases in which midwives summon medical help during the puerperium for rise of temperature are not notified as cases of puerperal sepsis. The majority of these cases are undoubtedly cases of mild sepsis. In addition it is probable that many rises of temperature are overlooked by the midwives, owing to their habit of visiting once a day only, and that in the morning. Taking everything into consideration, it would probably be fairly correct to state that at least three times as many cases of puerperal sepsis actually occur as are notified. The majority of these are undoubtedly mild cases, but a proportion are certified as dying of pneumonia or some other secondary complication. In addition many cases of phlegmasia

alba dolens are known to occur, and are never notified, although these are, of course, cases of puerperal sepsis. Many practitioners who write of having delivered so many hundreds of women without a single case of puerperal sepsis have been extraordinarily lucky, or have failed to consider any case septic unless the condition was a severe general septicæmia or pyæmia. The whole question is one of definition. A clear and authoritative pronouncement is needed, and has not yet been made.

Environment: (a) Attendance at Labour.

TABLE II.

Doctor and handywomen ..	14	Doctors' cases .. 38
Doctor and midwife ..	10	
Doctor and midwife (hospital) ..	11	
Doctor and relative ..	3	Midwives' cases .. 51
Midwife alone ..	30	
Midwife and doctor (called during labour) ..	12	
Midwife (institution) ..	5	
Medical students and midwife ..	4	

From the figures in Table II. it will be seen that omitting the institutional cases and those attended by medical students, doctors were primarily in attendance in 27 cases, or 30 per cent., and midwives in 42 cases, or 48 per cent. This must be taken with the fact that the midwives normally attend 65 per cent. of all confinements, so that the percentage of puerperal sepsis in midwives' cases is not unduly high.

Nature of Labour.

Normal (no interference beyond vaginal examination) ..	52
Instrumental ..	29
Version, manual removal of placenta, &c. ..	8
Total ..	89

These figures show that the presence of the doctor does not under present conditions in any way safeguard the patient. Dame Janet Campbell has drawn a picture of the methods employed by the medical practitioner which is absolutely accurate for working-class practice as a whole, and which has been confirmed in this inquiry. The use of gloves and sterilised gowns is quite exceptional, while the preparation of the bed and of the dressings, &c., is primitive, when considered in the light of modern surgical procedure. As a rule, too, all swabbing and cleansing of the patient is left to the nurse, who is frequently an untrained handywoman. The methods of the midwife leave much to be desired, but a higher standard could be obtained from her if a better example were set. The attendance during the puerperium is equally important with the attendance at labour, and here again both doctor and midwife are inclined to do too little. The doctor in a large proportion of cases leaves all the nursing to the handywomen, frequently not even taking the temperature. The midwife in her turn, though more efficient than the handywomen, is inclined to visit only in the morning and to omit Sunday. There is no suggestion here of the need for careful dressing, and the securing of efficient drainage for an open wound or wounds. No change in procedure is attempted even with a severe perineal or cervical laceration. After the ministration once in 24 hours of the midwife, the woman is allowed to change her own dressings and do what she can with the help of a neighbour.

The importance of careful nursing in the puerperium is well illustrated in the cases studied in this inquiry. In 52 of the 89 cases labour was normal, with no interference beyond the usual vaginal examinations, yet in 36 of these normal labours there was injury, incomplete evacuation, or both. Where the cervical injury occurred alone, as it did in nine cases, its presence was not even suspected, while the presence of placental and membranous fragments in utero was not considered possible, even in cases where considerable quantities were subsequently evacuated. The importance of careful dressing and observation during the puerperium, with early and energetic treatment, is obvious. The attendance and nursing in domestic midwifery practice are far below the hospital standard,

and taking this into consideration the actual amount of sepsis is very low.

(b) *Home Conditions.*—The small influence of the general environment of the patient on the incidence of puerperal sepsis is at first sight somewhat remarkable, but it is after all only another illustration of the greater liability to infection from a personal agent which is being so widely recognised in infective conditions generally. Probably the only important influence of environment on the incidence of puerperal sepsis is through the effect on the general health with a consequently lowered resistance, but even here the effect is seen less on the incidence than on the death-rate. Thus:—

<i>Health of mother in all cases (total 89)—</i>			
Good, 64 (71%)		Poor, 15	 Bad, 10
<i>Health of mother where death followed (total 19)—</i>			
Good, 11 (59%)		Poor, 3	 Bad, 5

The home conditions appear to be in themselves an almost negligible factor apart from the type of attendance and nursing available. In only three instances in this inquiry was it possible to account for the infection by the environment alone.

Local Conditions.

(a) *Injury.*—It is not easy to exaggerate the importance of this factor in the liability to puerperal infection. It is the most frequent cause of phlegmasia alba dolens and cellulitis. Very many cases of prolonged disability follow both these conditions, while no one can overlook the disability resulting from a badly torn and unrepaired perineum. The great majority of these cases are not notified as puerperal sepsis. It is only the more severe and generalised infection which is notified, yet among the 89 cases under consideration injuries were present in 44, or 49 per cent., and in 11 the injury appeared to be the only cause of the infection, there having been no undue interference or incomplete evacuation. The nature of the injuries was as follows:—

Perineal tear alone		11
Cervical injury alone		9
Cervical and vaginal injury		5
Vaginal injury		2
More than one injury including perineal tear		17
<i>Severity.</i> —Very extensive, 4; very severe, 12; severe, 15; slight, 13.		

Such injuries are in a majority of instances inevitable, but their presence should be ascertained, and when ascertained suitable treatment applied. The point is that no special care is employed to obviate or minimise infection with the result indicated. At the same time, there can be no doubt that with adequate antenatal care, including careful abdominal examinations, the larger proportion of the severe injuries could be eliminated, and with them the gravest risks to the patients.

(b) *Imperfect Drainage and Incomplete Evacuation.*—In this inquiry 49 cases, or 52 per cent., showed incomplete drainage or evacuation. This varied in degree, but in 25 cases considerable placental fragments were subsequently removed. It appears certain that in far the largest proportion of cases injury and imperfect emptying of the uterus play a predominant part. In fact, in only 25 of the 89 cases were neither present—i.e., in only 28 per cent.

While injury of a severe type was naturally found to a predominant extent in instrumental labours, it must be emphasised that such labours form only a proportion of those in which the two factors under consideration play a part in the onset of sepsis. The number in which both or one occurred was 65, or 73 per cent., and in 36 of these cases the labours were apparently normal without interference of any kind beyond the usual vaginal examinations.

(c) *Presence of Tumours.*—This is a comparatively rare complication, but it is one that should not be overlooked. Two cases with fibroids occurred in this series, and in both the tumours became infected, leading in one case to death. Both women were elderly multiparæ, and this serves to indicate the importance of antenatal examination even in this

class of patient, since this would have obviated much of the risks.

General Health and Hæmatogenous Infection.

Reference has already been made to this under "Environment," and it is obvious that a lowered resistance must result from any condition leading to general debility. Rather unexpectedly, however, the effect appears as making the prognosis worse after infection has occurred, rather than increasing the risk of sepsis. These women if they escape sepsis suffer from post-puerperal anæmia and debility, but no evidence is available that in the absence of other factors they suffer from a greater liability to sepsis. This modifies one's views as to the part played in hæmatogenous infection in puerperal sepsis. Probably with a local factor the presence of an infective nidus elsewhere increases the liability to, and the severity of, a puerperal infection, but without a local factor its occurrence appears problematical, since septic foci of one kind or another, especially of the mouth, exist in such a high proportion of mothers with no ill-effects. In this series one case was very suggestive. The patient suffered from a whitlow at the onset of labour, and subsequently died with a definite septic endometritis and thrombosis in the left broad ligament. There was, however, placenta prævia, and a bipolar version was performed, considerable hæmorrhage occurring.

Epidemic Form of Puerperal Sepsis and the Rôle of the Carrier.

Undoubtedly the part played by the carrier in puerperal sepsis is now of considerably less importance than in the past. Owing to the general recognition of the danger and the strict supervision of midwives, outbreaks are less frequent, but they still occur. The danger of carrying infection through an attendant from patient to patient is, of course, a very real one, and is constantly being illustrated in small and inefficiently run maternity homes. There is, however, another type of carrier infection which is in a sense even more dangerous since it is not so clearly recognised—viz., where the attendant suffers from an infective condition, such as a septic throat, a nasal catarrh or a sinusitis, and produces septic infection among her patients. These may be mild cases or the reverse. In this series such an outbreak occurred. A probationer nurse doing her district training attended, while suffering from a cold and sore-throat, several confinements which subsequently developed symptoms of mild sepsis. One of these cases was notified. The patient suffered from marked parametritis and phlegmasia alba dolens with considerable pyrexia. Medical officers whose duty it is to supervise the work of midwives are familiar with this type of puerperal sepsis; it is difficult to guard against, as the possibility of its occurrence is not sufficiently emphasised in midwifery training.

Early Diagnosis and Treatment.

The above may be taken as the main factors concerned in the onset of puerperal sepsis. Sepsis having actually occurred, however, the important thing is the prevention of death, disability, and spread. Of the last nothing more need be said, but the importance of early recognition and treatment is so paramount that insistence on any point bearing on them cannot be omitted. In this connexion the time of onset is of interest. In the cases investigated in this inquiry the onset in 79 of the 89 cases was in the first week, while in 52 cases, or 57 per cent., the onset was within the first three days. Yet of the 72 cases sent to hospital only 32 were sent in the first week. There is undoubted delay in many cases. On the other hand, in eight cases the onset definitely occurred after the eighth day, and these late cases are important, since an impression appears to be prevalent among midwives that puerperal sepsis does not occur after the eighth day. The death-rate in this series was 21 per cent. Nineteen women lost their lives. Contrasted with the death-rate of other

infections this is very high. Among these deaths, the points which call for special comment are the high proportion of normal labours, 49 per cent., and the high proportion of women in bad health, 42 per cent.; 25 per cent. of the deaths were in primiparæ. The actual cause of death was general peritonitis in 42 per cent. of the cases. In all but one case there was delay in securing hospital treatment, which certainly in a proportion of the cases was apparently responsible for the fatal result.

Antenatal Care.—In no case was any antenatal examination made by a private medical practitioner nor was the urine examined. In 19 cases the patients had attended clinics at hospitals and child welfare centres, and in four cases midwives had examined the urine. This was the extent of antenatal care in this series.

Abortions.

During the period of the inquiry 35 abortions were notified as puerperal sepsis; of these 25 were septic cases, and four deaths occurred. Abortions, however, present rather a different aspect of the problem and should be considered separately. One point requires emphasis, however—the need for early and skilled treatment.

Conclusions.

It is clear that the prevention of puerperal sepsis and a diminution in its mortality are dependent upon an improvement in (a) management of and attendance at childbirth; (b) nursing in the puerperium; (c) provision for treatment; (d) antenatal care.

(a) *Improved Management of and Attendance at Childbirth.*—A normal labour is a physiological event and so the presence of the medical attendant is not required. It borders, however, on the pathological, and for this reason a skilled and highly trained midwife should be in attendance, capable not only of using surgical cleanliness during labour but of readily diagnosing any untoward happening requiring medical intervention. Such medical intervention, when required, should be given by an obstetrical surgeon specially trained for the work, since his aid is sought only when the case is already pathological. It has recently been suggested by Prof. Louise McIlroy that the situation should be met by appointing whole-time obstetricians in the public health service who could be called in by the midwife. While agreeing with Prof. McIlroy that it is only the obstetrical surgeon who can suitably deal with these cases, one cannot agree with her as to the method of supplying the need. The public health service, as at present constituted, is not a national service, all its activities depending on local authorities, whose views diverge widely on every medical question, and few of whom can be relied on to take long views. We already have a national medical service which is uniform throughout the country, and which is centrally controlled and guided—viz., the National Insurance Medical Service. Under the insurance scheme something is already being done for maternity, in the form of maternity benefit. Additional benefits—e.g., dental benefit—are being included in the scheme. There appears to be no sound reason why an approved maternity service should not be provided, replacing if need be the present maternity benefit. Under such a scheme a panel of midwives could be arranged whose work would require to conform to a definite standard, and at the same time a panel of obstetrical surgeons with special training and experience could be arranged, not only to attend the difficult cases but to undertake antenatal care in every case. Antenatal care should not be left to the midwife. She can do a limited amount, and should be expected to do that amount, but a thorough medical examination is required in every case in the later months of pregnancy. There appears to be no reason why public health authorities should not when possible allow suitable child welfare centres to be used for such antenatal work where such an arrangement is considered convenient. Such a service would put midwifery practice on an entirely new basis. While encouraging younger medical men

and women to specialise in obstetrical work, it would be no hardship as far as those doctors are concerned who are already specially interested in this work. It need not be a condition that other forms of practice are necessarily given up, but it should be clearly understood that a general panel of more than 500 is not allowed. It is not possible to combine specialised obstetrical work with a large panel practice. In rural areas some modification of such a rule may be required, but there should be no serious difficulty in cities. The need for more maternity beds is constantly being emphasised, and is an obvious and urgent feature of any scheme for an improved midwifery service. The cost of such a scheme need not be prohibitive, while its influence not only on maternal mortality in childbirth but on the incidence of neonatal deaths among infants should be considerable.

(b) *Improved Nursing in the Puerperium.*—A detailed consideration of a series of cases must impress the importance of this factor on any observer. The proportion of normal labours is so high that some other factor must come into play apart from the mismanagement of labour. It is a point on which sufficient stress does not appear to have been laid. Probably medical opinion has failed to realise the actual circumstances, not so much from lack of knowledge as from lack of visualising the conditions. This has already been dealt with, however. Under present conditions no midwife can give adequate attention in the puerperium. In order to earn her living she must take an excessive number of cases. If improved nursing is to be secured improved payment is essential. It becomes once again a financial question.

(c) *Improved Provision for Treatment.*—The provision made by many local authorities for the treatment of puerperal sepsis is inadequate and unsuitable. It is not possible for the medical attendant to insist on his patient consenting to removal unless he feels that such removal will lead to satisfactory treatment by skilled obstetricians. The mortality of the condition cannot be lowered without improvement in this direction.

(d) *Improved Antenatal Care.*—While antenatal care is probably of less importance than the previous factors, there is no doubt that a considerable percentage of cases could be prevented by ascertaining the likelihood of a difficult labour and making suitable preparations. The importance of antenatal care is seen even more markedly in the other causes of our high maternal mortality. A better training in midwifery for both doctors and midwives is being urged in every direction, and it is undoubtedly the first and most important step. But in this paper an attempt has been made to consider other aspects of the problem.

OBSERVATIONS ON SOME CASES OF POST-ENCEPHALITIC PSYCHOSES.

By P. K. McCOWAN, M.D. EDIN., M.R.C.P. LOND.,
D.P.M.,

ASSISTANT MEDICAL OFFICER, WEST PARK MENTAL HOSPITAL,
EFSOM.

UNDER an arrangement originally emanating from the Board of Control the majority of cases of post-encephalitis in L.C.C. mental hospitals have been transferred to West Park Mental Hospital. A study of these cases has been made in the hope that some new light might be cast on the intricate problem of mental sequelæ in this disease. The number of cases collected is surprisingly small, even allowing for the fact that not all cases have so far been sent to West Park. Nine male and three female cases comprise the total number. In the case of three of the males the diagnosis is very doubtful, and in another, a man of 63 years of age, paralysis agitans is present, but unless the theory is held that this and encephalitis lethargica

are one and the same, there is nothing to suggest that the condition is post-encephalitic. This leaves eight cases which have undoubtedly suffered from encephalitis lethargica, and the following observations concern these only.

The two points on which I think these cases throw light are, first, the supposition of the progressive nature of this disease, and second, how far these psychoses can be regarded as true sequelæ of encephalitis lethargica (E.L.). No fewer than five of the eight cases support the contention that the virus continues present and potent in the central nervous system for considerable periods after the subsidence of the acute symptoms, somewhat as in the case of "parasyphilis."

Cases Illustrative of this Supposition.

CASE 1.—A woman, aged 36, married, had E.L. in 1920, when she was in deep stupor for two months. Admitted to Cane Hill Mental Hospital August 1st, 1922, with Parkinsonian syndrome present, right pupil dilated and practically fixed, left pupil normal. She had good insight into her condition, appreciated the enfeeblement of her self-control, was apathetic, but exhibited little or no dementia, and could give a good account of her illness. She has gradually become worse, is now totally dependent, faulty in her habits, very apathetic, and exhibits much dementia. She improved for a time on hyoscine, but this only delayed her downward course temporarily.

CASE 2.—A single man, aged 50, E.L. in March, 1924, with drowsiness, giddiness, diplopia, macropsia, ptosis, nystagmus, irregular sluggish pupils, restless and fidgety especially at night, drowsy by day, sleepless by night, sometimes an occupational delirium. He slowly improved and was sent to a convalescent home in May. Three weeks after being sent home apparently well, in July, he became depressed and attempted suicide by cutting his throat, and was sent to Claybury Mental Hospital. His physical signs are now very slight. His pupils are small, equal, irregular, react sluggishly to L. and A., convergence fair, lateral nystagmus; slight incoördination of upper extremities; slight paresis of facial muscles; deep reflexes normal, superficial including palatal and pharyngeal absent. He now exhibits a paranoid psychosis, is depressed and agitated, has auditory hallucinations and delusion that he is accused of "messing about with little children," and other immoralities, and thinks he has enemies who are plotting against his life. He is drowsy by day and sleeps badly, but is capable of occupying himself in the grounds. He is a mental defective who only reached standard II. at school, and his intellectual enfeeblement is doubtless due to his mental deficiency. Hyoscine appeared to aggravate his mental symptoms and had to be discontinued after a few weeks.

CASE 3.—A single man, aged 30, had attack of E.L. in March, 1924, with constipation, fever, herpes left shoulder, diplopia. After three consultations, one at St. Bart's, it was decided that this was not E.L. He improved rapidly, and had returned to work by end of April. A robbery which took place at his workshop upset him very much and aggravated the "neurasthenia" present, and another consultation now led to a diagnosis of E.L. His present physical signs show the distinct progressive nature of his disease with involvement of region of third nucleus (ptosis, diplopia), pyramidal tracts (K.J.'s +, Babinski), facial nerve nucleus (facial flaccidity). His emotional facility and dementia show the involvement of his basal ganglia and cerebral cortex respectively. He is acutely depressed, full of morbid fears, has hypnagogic hallucinations which usually take the form of grotesque animals, and which terrify him though he recognises their hallucinatory nature. He is much occupied by pains in his abdomen and chest which he describes as "pulling." His memory is very bad, and he gives a very poor account of himself and his illness. He is often difficult with his food, sometimes faulty in his habits, and is continually asking to be allowed to die. Hyoscine seemed to make him worse.

CASE 4.—A single man, aged 50, had E.L. in May, 1920, or in the patient's words he was "ill with influenza and went dotty." He showed inversion of sleep rhythm, and was very noisy by night. After five weeks he was sent to Claybury Mental Hospital, but was discharged after six months and returned to work. He still felt "nervous and dull," however, and had to attend Guy's Hospital as an out-patient with the following symptoms: Insomnia, feeling of agitation, fear of traffic, attacks of "shaking all over," constipation, and retention of urine for 36 hours on one occasion. He had to discontinue work after four months, and seven months later he was again certified and was sent to Long Grove Mental Hospital. He now exhibits Parkinsonian syndrome with its

mask-like face, general spasticity, festinant gait, retropulsion, pill-rolling movements, cramps in legs, athetoid movements in arms, coarse tremors of hands, slight intention tremor, slurring monotonous articulation. His deep reflexes are sluggish, his superficial normal; pupils moderate size, R. > L. irregular, react sluggishly to L. and A. Mentally he is dull, depressed, solitary, only speaks when spoken to and then in monosyllables, is morbidly introspective, very childish, very dependent, and exhibits emotional facility. He is of degraded habits, very untidy and given to spitting about on the floor. He has a very bad family history, one brother being insane, another having died insane, also a paternal uncle; his mother was a drunkard. Hyoscine 1/150 gr. daily makes him feel brighter and less spastic.

CASE 5.—A single man, aged 22, had E.L. in March, 1924, with lethargy, ocular symptoms, &c. He was able to return to work in July feeling quite fit, but in September he had to give up work and has become progressively worse since then. He now presents the Parkinsonian syndrome with its characteristic gait, attitude, articulation, &c. In addition he has myoclonic jerks in all four limbs. He is extremely depressed and miserable, is aurally hallucinated, and has delusions of persecution. He has made two determined attempts at suicide by strangulation, and still harbours strong suicidal tendencies. There is no dementia in evidence.

In Cases 1 and 2 there has been no progression as far as the physical signs are concerned, whereas in Cases 3, 4, and 5 these have become more extensive, and especially in Case 3. In all four have the mental symptoms become more marked, and if these psychoses are true sequelæ in the sense of being due to changes in the central nervous system caused by the virus of E.L., then it must be supposed that the virus has continued present and actively potent in the cerebral cortex of these patients. Certain significant facts, however, are present in two of these five cases to throw doubt on the nature of their psychoses. I refer to the stability of the central nervous system of these patients prior to their attack of E.L. Thus Case 4 has an insane heredity, and Case 3 is a mental defective, and his psychosis is very typical of a form of mental disease often got in mental defectives from mental stress.

Of the three other cases two are mental defectives, so that out of the eight cases five may be regarded as having been of unstable mental equilibrium prior to their attack of E.L., and in these cases it is very possible that their psychosis is not a true sequela, but should rather be regarded as of psychogenic origin, the mental stress due to their illness being in the nature of a psychic trauma. One of these mental defectives is a woman of 35, who exhibits the Parkinsonian syndrome, and a definite dementia superimposed on her mental deficiency. The other is a boy of 10 years of age, who had his attack in May, 1924, with ocular symptoms, inversion of sleep rhythm, myoclonic twitchings of the legs, &c. He passed into the "apache" type of Hall, with homicidal and suicidal tendencies. He attempted to cut his throat with a large knife. Under institutional life his behaviour has improved considerably, but he has periods lasting for several hours, and especially frequent by night, when he is aurally hallucinated, confused, restless, talkative, and noisy.

It is of interest to note that three of these eight cases attempted suicide and that another has strong suicidal tendencies. Suicide is regarded as an extremely rare occurrence in epidemic encephalitis. Some authorities hold that a true systematised delusional state is not got in post-encephalitic cases, but Cases 2 and 5 exhibit this state. As previously noted, it is, of course, possible that the psychosis of Case 2 is not a sequela in the true sense of the word. Some observers hold that dementia is not got as a post-encephalitic mental sequela. Cases refuting this statement have been recorded in the present series.

The mental symptoms observed in the acute phase of the disease are largely of toxic origin, and if a definite psychosis results it is very similar to cases of toxic psychoses from other causes—e.g., typhoid fever. One of the female cases in this series was of this nature, and she has recently been discharged, her

mental symptoms having cleared up, though she still presents the Parkinsonian syndrome.

Conclusions.

1. Certifiable insanity is extremely rare as a sequel to E.L. 2. It is highly probable that the virus of E.L. has the power of remaining in the central nervous system in a potent form long after the subsidence of the acute symptoms. 3. Many cases of insanity following E.L. may not be true sequelæ, the encephalitis merely acting as a precipitating psychic cause. 4. The possibility of suicide following E.L. must not be lost sight of. 5. Systematised delusions and dementia are sometimes found in post-encephalitic psychoses. 6. Psychotic symptoms during the acute phase of the disease are toxic in origin and of much better prognosis than post-encephalitic psychoses. In the very rare event of a recovery in the latter it is practically certain that the case would not be one of a true sequela but of the secondary psychic type.

I take this opportunity of thanking the medical superintendent of West Park Mental Hospital for permission to publish these preliminary observations.

GLYCOSURIA AND PRURITUS

DEPENDENT UPON LATENT DISEASE OF THE APPENDIX.

By W. SOLTAU FENWICK, M.D.

A SURVEY of the clinical notes of 4000 cases of visceroptosis which had come under the writer's observation brought into prominence several interesting results of this abnormal location of the abdominal organs. Colitis existed in about 30 per cent. of all cases after the age of 30 years, although in many instances it was so slight in character that it would have escaped attention had it not been for the exaggerated importance attached to the presence of a little mucus in the stools. Appendicitis was noted in 23 per cent. of all cases and was equally common in the two sexes. In rather more than one half of the cases the appendix had already been removed, in some instances for definite symptoms of inflammation, but more often, apparently, with the expectation of curing the coexistent dyspepsia. The fact that chronic inflammation of the appendix in visceroptosis is usually an expression of a diffuse catarrh of the entire colon serves to explain why the operation is rarely followed by permanent amelioration of the gastro-intestinal disorder. When the appendicular disease remains free from clinical manifestations for many years it is sometimes accompanied by at least two interesting phenomena which do not seem hitherto to have attracted attention—namely, glycosuria and pruritus.

Glycosuria.

The ætiological connexion between sugar in the urine and disease of the appendix was first brought to the writer's notice in 1902 by the case of a young man who had exhibited intermittent glycosuria for five years. At the end of that time an operation was performed for acute appendicitis, with the surprising result that the sugar disappeared from the urine within a month and never returned. The same sequence of events ensued in four other cases, and further experience seems to indicate that the condition is not so rare as the writer had supposed it to be. In all the cases seen by him up to the present time the patient was the subject of congenital gastro-coloptosis accompanied by mild chronic gastric hypersecretion. No history suggestive of appendicitis was ever obtained nor were any signs of the disease detected. Male subjects exceeded the female by nearly three to one, a fact which is noteworthy in view of the much greater liability of women to visceroptosis. The average age at which the patients came under observation was 22 years, and in several

instances the sugar had first been detected at a medical examination for life insurance. Thirst and polyuria were never prominent symptoms, and the amount of urine voided in 24 hours seldom exceeded 60 fluid ounces. As a rule, complaint was made of general debility, lassitude, mental depression, sudden variations in the weight of the body, and occasionally of pain in the lumbar spine. A sudden access of muscular weakness, attended by loss of weight, frequently heralded a recurrence of the glycosuria. The amount of sugar in the urine usually varied from 0.08 to 0.3 per cent., and its existence was never accompanied by any notable increase of the sugar in the blood. It was more often detected in the urine passed before midday than at other times, and frequently disappeared entirely for several weeks in succession. At operation the appendix invariably showed signs of chronic inflammation, but no calculus, ulceration of its mucosa, or peritoneal adhesions were recorded unless there had been a recent attack of acute inflammation. After operation the sugar disappeared from the urine and did not recur in the cases which remained under observation, which in one instance extended for nearly 20 years. It seems probable that the gastric hypersecretion excites inflammatory changes in the pancreas in persons who possess a proclivity to such disease, in the same way that other varieties of the gastric disorder are often followed by glycosuria and even by genuine diabetes.

Pruritus.

Another rare and peculiar condition which sometimes develops as a result of latent appendicitis is intense itching of the skin. Four characteristic examples occurred among the series of cases to which reference has been made, and several others of a similar type have more recently come under the writer's observation. The complaint seems chiefly to be confined to women about middle age, and when once established it remains persistent and defies all ordinary methods of treatment. Its characteristic feature is excessive irritation of the skin over the lower part of the abdomen, which develops about one hour after the patient has retired to bed and continues with scarcely any intermission for several hours. The irritation is often described as being "under the skin," and was likened by two patients to the sensation of a maggot burrowing its way through the subcutaneous tissues. It is never accompanied by a visible eruption, and the most energetic scratching and rubbing afford no relief; but the application of pressure or hot fomentations occasionally allays the pruritus for a time. In other cases, or at other times, the sensation is one of intense scalding or burning, sometimes accompanied by hyperæsthesia of the skin, while occasionally the irritation attacks in succession the buttocks, flexures of the forearms, popliteal spaces, or the interscapular region. In one case a woman's existence had become almost intolerable by reason of the itching of the skin of the abdomen which occurred one hour after going to bed and persisted until 5 o'clock in the morning, when she was suddenly seized with acute appendicitis which necessitated removal of the appendix. A week later it was found that there had been no nocturnal pruritus since the operation and since then the complaint has never recurred. The same result ensued in the other cases. In yet another instance where the typical pruritus over the abdomen at night led the writer to advise appendicectomy, the patient was attacked with appendicitis in the country, which subsided under medical treatment. On her return to town six months later she stated that the irritation had gradually subsided during convalescence and was then a negligible symptom. In this case it would seem that the acute inflammation of the appendix had either destroyed the source of some special toxin or had so impaired the nervous elements of the appendicular mucous membrane as to inhibit the production of reflex phenomena. In more than one case the appendix after removal was found to be packed with faeces of stony hardness.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF PSYCHIATRY, NEUROLOGY, EPIDEMIOLOGY, AND DISEASES OF CHILDREN.

A COMBINED meeting of these Sections was held on Jan. 27th, Dr. R. H. COLE, Vice-President of the Section of Psychiatry, in the chair. The adjourned¹ discussion on the

MENTAL SEQUELÆ OF ENCEPHALITIS LETHARGICA

was opened by Dr. J. C. SPENCE, who approached the subject from the aspect of the child patient and of prognosis. In his experience 30-40 per cent. of the cases were under 12 years of age, and the after-results could be divided into two groups according to whether the incidence was before or after the third year. In infants under 3 a severe amentia was usual, but after the fourth year a true idiocy had never been seen by him, and the impairment of the intellect was not a marked feature, such cases being characterised rather by emotional and volitional defects. In the Parkinsonian type there was apathy, accompanied by diminished volition, lack of initiative and interest, while in the difficult or apache child there was perversion of volition accompanying the restlessness, noisiness, and impudence. Dr. Spence stressed the danger of pronouncing a cure prematurely, quoting a case which showed a relapse to the "difficult child" condition five years after the acute attack, and after three years of apparent normality. In the epidemic in Newcastle in the spring of 1924 they had found that the old oculo-lethargic type of case no longer occurred, the common onset being of an acute painful myoclonic type, with difficulty diagnosed from acute rheumatism or an acute abdomen. Such cases showed widespread involvement of the spinal cord post mortem, but were less liable to mental sequelæ. Dr. Spence referred to a statement made by Dr. Donald Paterson and himself (*THE LANCET*, 1921, ii., 491) to the effect that the longer the acute stage of the illness the greater the degree of mental disturbance to be anticipated; this he no longer believed to be true; severe permanent damage to the intellectual functions might result from an acute illness of two days' duration only, but the great factor in prognosis was the night restlessness, which seemed to be directly proportional to the subsequent mental derangement. The persistence of physical symptoms—i.e., Parkinsonism, rigidity, stolidity of features—was accompanied by some mental sequelæ—apathy at least, if not more marked mental failure. Diagnostic pitfalls, in addition to the well-known ones of acute rheumatism, influenza, &c., included juvenile general paralysis, cerebro-spinal fever, and pellagra, cases being on record where these latter conditions had been taken for encephalitis lethargica.

Dr. C. WORSTER-DROUGHT agreed with previous speakers that certifiable conditions were rare, taking the form of progressive dementia, delusional states or hallucinatory confusion if present. The minor degrees of psychosis were, however, common, with apathy, lack of spontaneous interest and initiative, and rapid fatigue on mental effort. He believed that the apathy was often more apparent than real, and that there was very little impairment of intellect, the main feature being a retardation in the somatic efferent component of the nervous system. He referred to the experiments carried out by Dr. D. N. Hardcastle and himself, an account of which appeared in the *Journal of Neurology and Psychopathology* for August, 1924. They had found that the psycho-motor reaction was distinctly lengthened (by 50 per cent.), but that the cerebration

time for selection was normal or a little less than normal. Only three of their 19 cases had shown a subnormal result in general intelligence tests, and these had presented defects under the headings of Reason and Memory. He considered that the psychoneuroses following encephalitis lethargica were due to diminished inhibition, rendering manifest a condition previously latent, but controlled. The symptoms were generally apprehension, undue self-consciousness, a sociability or terror-dreams. Moral deterioration was probably to be ascribed to the same cause, and the prognosis in this condition was good. He agreed with the necessity for giving a very guarded prognosis, and referred to a case showing mental lapse after four years of apparent recovery.

The Psychological Aspect.

Dr. D. N. HARDCASTLE remarked that 17 of the 19 cases experimented on by Dr. Worster-Drought and himself were of the Parkinsonian type. The aspect he particularly wished to stress was the psychological. Twelve of the cases showed psychoneurotic symptoms such as anxiety, phobias, and terror dreams, and in two of these cases the phobias and anxiety had been removed by psychotherapy, a marked improvement in their condition being thus produced. No alteration to the organic brain lesion could have been effected by such measures, and Dr. Hardcastle suggested that the mental changes in this type of case were not so much dependent on direct injury to the cortical areas as on a failure of adaptation to the environment, which was rendered a much more difficult task by the crippling lethargy and psychomotor retardation. Prof. Arthur Hall had likened the difficult child to a psychasthenic, and Dr. F. C. Shrubbsall had called attention to similar psychoneurotic symptoms following influenza—viz., rapidity of fatigue, lack of concentration, failure of continuity of attention, &c. The characteristic disturbance of the sleep-cycle had also been noted among shell-shocked soldiers. Referring to the statement that there was impairment of memory for the period of the illness, Dr. Hardcastle stated that he had not found this to be the case in any greater extent than is usual in other serious illnesses with delirium. Patients gave detailed histories of their attack, broken only by the periods when they were actually asleep. The onset of the mental changes did not coincide with the onset of fever or with defervescence. Often there might be an intervening period of apparent normality before the lethargy was established and with it the first appearance of mental symptoms. Dr. Hardcastle agreed with the observation of Jones and Raphael that a psychoneurosis latent before the illness might become apparent after it, and he applied this also to a latent psychosis.

Dr. E. MAPOTHER reported on 45 cases which had come under his care at the Maudsley Hospital. These he divided into three groups: (1) Mental anergia, ranging from difficulty in sustained attention to morbid sleep; (2) morbid restlessness; and (3) demoralisation. He pointed out that the latter two groups were far more likely to behave in a manner necessitating conveyance to a mental hospital, and that therefore the proportion of this type met with in such institutions did not give a true picture of the proportion occurring on the whole. Dr. Duncan, in following up the after-histories of cases at the London Hospital, had formulated the rule that positive mental symptoms at the onset were negligible for prognosis, but that negative early symptoms were very ominous; this ruling had not been supported by experience at the Maudsley, and no satisfactory formulations had been obtained. Marked restlessness was most common in children under 8, and demoralisation in cases between 8 and 20 years of age. Both were rare in adults, in whom anergia was the commonest symptom. Anergia seemed to be most commonly present in association with organic Parkinsonism, which was not usually coincident with marked restlessness, but in both cases the reverse condition was sometimes met, and both anergia and restlessness might be paroxysmal

¹ See *THE LANCET*, Jan. 24th, p. 181.

or even alternate. He agreed with previous speakers that none of the post-encephalitic cases resembled the ordinary psychoses, the chief symptoms being very marked conative disturbances, with spontaneous variations from time to time. In the absence of somnolence, negative intellectual disturbances were slight, and were mostly to be explained by inattention. Delinquencies were the result of the failure of inhibition, the wish passing almost directly into the act, while the individual recognised abstractly the nature of his behaviour. The children were markedly free from fear, the strongest of the inhibitions. There was no evidence of delusions or hallucinations or of dreams in the drowsy states, with the exception of one case—a barman who ejaculated at intervals "Time, gentlemen, please!" The lying met with seemed to be conscious lying; unlike the hysterical phantasy, half-believed by the patient. On the whole, apathy seemed commoner than excess. The one case of attempted suicide ascribed her effort to her distress at her total loss of feeling. The spontaneous variations in the symptoms suggested a continuous active process and was responsible for the rarity of certification; the cases only needed institutional treatment if they were incapable of self-support or a nuisance to their neighbours. The diagnosis from functional conditions was very hard and should depend on the presence of physical signs—Parkinsonism or nerve palsies—however tempting mental symptoms might be. There was much increase of capacity possible with increased attention and effort, habit and automatism playing a distinct part in the maintenance of symptoms of inefficiency.

Dr. J. G. FORBES referred to three cases in which encephalitis lethargica complicated epilepsy, and to the difficulty of distinguishing between post-epileptic conditions and the lethargy of encephalitis.

Dr. A. GILMOUR described two cases of late mental sequelæ after apparent recovery.

Dr. H. CRICHTON-MILLER referred to the beneficial effect of hyoscine on apathy and anergia and asked how this action was explained, since there seemed no other instance of reintegration of the psyche resulting from the administration of a sedative.

Dr. ALICE M. HUTCHISON asked if there was any consensus of opinion as to how long children should be kept from mental work after an attack.

Dr. WORSTER-DROUGHT remarked that he had had four cases of epilepsy following encephalitis lethargica attending the West End Hospital. He had found that hyoscine lessened tremors and rigidity, but that it was necessary to continue its administration permanently.

Dr. P. C. P. CLOAKE observed that there was very often some history of psychic trauma at or about the time of onset of the disease. He disagreed with Dr. Worster-Drought's conclusions as to the absence of psychic retardation, believing that tests designed to eliminate motor phenomena showed considerable psychic involvement, acting primarily in the region of the psychic "flat" which sets an action going. He had found hyoscine active only on injection, and ascribed its effect to the sedative action on the cerebrum and motor nerve-endings in muscle, and doubted whether it had any effect on the psychic condition. He considered that the longer children were kept from school the better, and reiterated the opinion expressed in his earlier paper, that the essential feature of the disease was the organic injury to the cortex resulting from the action of a toxin, whereby the highest functions (e.g., inhibition, adaptation) were most damaged.

Dr. COLF, in concluding the discussion, raised the question of the infectivity, and the reluctance of some institutions to admit cases for this reason. He also pointed out the difficulty of deciding whether a child had better be certified under the Lunacy or Mental Deficiency Act, and expressed the opinion that hyoscine should be used in emergencies only, as it had a deteriorating effect on the nervous tissue and

made the patient very uncomfortable. Although it undoubtedly did good in Parkinsonian cases, he thought the cure worse than the disease. He advocated the use of urotropine.

SECTION OF UROLOGY.

A MEETING of this Section was held on Jan. 29th, Mr. CYRIL A. R. NITCH, the President of the Section, being in the chair, when Dr. N. S. FINZI opened a discussion on

RADIOTHERAPY AND ELECTROTHERAPY IN DISEASES OF THE BLADDER AND PROSTATE.

He said he considered that there was a great future for radiotherapy, at any rate in diseases of the prostate. Radium could be used on the skin, over the skin in the region of the pubes and sacrum, and even the perineum, the latter being extraordinarily sensitive to radiation. Used in this way, however, radium was ineffective unless given in large quantities and by several ports of entry. There must be protection afforded by a pad of felt or wax 2 cm. from the skin. A dose of 500 millicuries should be used. Radium had also been used per rectum, but on account of the sensitiveness of the rectal mucous membrane and the fact that burns occurred without effective result, it had now been given up. Still, in 1909 he succeeded in securing a successful result by this method in a case of tumour of the prostate region. The tumour was probably a recurrence of a teratoma of the testicle, the testicle having been removed some time before in South Africa, and the notes of the case could not be obtained. That patient was certainly alive two years ago and probably was still living. Seven years after the treatment there was a degree of rectal stricture.

In attempting to give effective doses of radium per urethram so much sloughing resulted as to constitute a danger; he believed this route had been generally abandoned in prostate cases. Even as an adjunct to other methods, the urethra tended to receive too large a dose, and outlying regions of the prostate too small a one. He suggested, in 1910, the perineal route for burying radium in the prostate, but he was unable to get it carried out. During the last few years that method had been used in Brussels, platinum needles being introduced by an incision in the perineum. Multiple needles ensured a more uniform distribution of the irradiation over the required area.

With regard to X rays, the modern method was to use greater filtration—i.e., 0.5 to 0.8 mm. of copper with 3 mm. aluminium, and at the same time to use more penetrating rays by employing a higher voltage. Also, some eight or ten portals of entry were used. Where multiple portals could not be used, and the front, back, and two sides were the only directions available, the tube was placed at a greater distance and larger fields secured. This was the means used when the disease was widely spread in the pelvis. In some cases a combination of radium and X rays was of distinct value, as also was a combination of diathermy and radium.

The Choice of Methods.

For simple enlargement of the prostate radium had not been largely used, as its external application had little advantage over X rays, and since very large quantities would be required, expense was a consideration. For this condition the embedding of radium in the prostate possessed no definite advantages over ordinary operative procedures. Moreover, if applied per urethram, it might cause ulceration, as also if used per rectum. X rays constituted a very suitable method of treating these simple enlargements, and possessed certain advantages over operation, such as (1) there was practically no primary mortality; with careful administration of the rays it was less than 0.1 per cent.; (2) there was not usually a prolonged convalescence, and the patient need not lie up; (3) no suprapubic opening was needed, and if complete retention was imminent a catheter could be tied in; (4) there was no danger of hæmorrhage afterwards, and the only skin damage resulting was a slight erythema.

There were some disadvantages attaching to X ray treatment of simple enlargements. Though in his cases one treatment had sufficed, it might not be so in every case. If subsequent operation should be required, it was conceivable that a previous application of the rays might make such surgery more difficult, on account of the fibrous formation around the prostate. The full benefit of the rays was not secured until three months after the application. And there was the possibility of treating in this way a case which was malignant. Small doses of X rays might increase cystitis and other inflammatory conditions. Considerable cystitis contra-indicated the use of the rays.

For malignant prostatic disease, multiple needles embedded in the prostate were being used in Belgium, and often in conjunction with X ray irradiation from the exterior. The perineal route was employed, and the asepsis must be most rigid. X rays by new means gave much promise for malignant prostate; he had seen improvement continue for a year after the use of the rays. For cases with a few papillomata of the bladder diathermy had supplanted radium. The difficulty was to secure homogeneous irradiation to the involved area.

In malignant disease of the bladder he had seen great relief follow the use of radium. It was used via the urethra, being placed in position under the guidance of the cystoscope, and was sometimes supplemented by doses per rectum or vagina. Subsequent applications had much less effect than the first. If operable, cases of malignant disease of the bladder should receive surgical treatment, and papilloma of the bladder was best treated by other methods, unless too large a surface of bladder wall was involved.

Discussion.

Dr. J. H. D. WEBSTER said that malignant disease of bladder and prostate constituted most difficult problems because the radiologist was not consulted until symptoms had lasted two or three years, so that the most promising stage had long passed. In only 2 per cent. of prostatic cases was the disease, when seen, confined to the prostate. In some reported cases, two weeks after radium had been employed in the form of small tubes for 900 mg. hours there was no evidence of malignant disease left, though in some of the sections a number of viable cells were still found. In America a preliminary X ray irradiation was given from umbilicus to symphysis, back and front, the dose being as large as the skin would stand, short of causing a burn. Radium needles were then inserted suprapubically or through the perineum. Americans removed growths of the bladder by diathermy first, then buried radium tubes into the base of the ulcer. Post-operative irradiation seemed to hold out some hope.

Dr. REGINALD MORTON said the radiologist did not confine himself to one technique. In malignant disease he was strongly in favour of giving a full dose of X rays at the earliest possible moment, as in cancer dissemination was the greatest complication which could arise. So long as the lesion remained local there was some hope. He was against temporising by giving fractional doses in these cases. Simple adenomatous enlargement of prostate responded well to treatment, and with proper technique good results ensued in nearly every case. He was not now speaking of fibrous enlargements due to infection. A single full dose ensured good results in three to six weeks; it was not necessary to administer such a large dose as to cause definite reaction. In the Erlangen method much stress was laid on accurate measurement of doses, though there was always a possible 15 per cent. margin of error. The manner in which a particular case would behave could not be forecast. More must be done in the way of preparing patients beforehand for irradiation and looking after them subsequently; 95 per cent. of the malignant cases passing through his hands were so far advanced that nothing beyond temporary amelioration could be expected. No real progress could be made in this department of work unless cases were seen at a

much earlier stage, when there could be some hope of success; there should be an earlier and closer co-operation between the surgeon and the radiologist. As a class he considered that malignant disease of the prostate was favourable for radiation. He had not had such favourable results in malignant disease of the bladder; a large proportion of those cases were infected, and this complication rendered them hopeless. Success in this treatment depended on a healthy and vigorous reaction of tissue.

Dr. BROWN CARFIELD spoke of using 50 mg. of radium bromide enclosed in a tin tube for prostatic disease. He discouraged hurried treatment with radium and said it was important to avoid any destruction of tissue. Radium seemed to act by causing constriction of blood-vessels. He did not view with favour the use of a number of radium needles.

Mr. CLIFFORD MORSON said he thought it would be agreed that suprapubic prostatectomy in the hands of an expert was attended with excellent results, and could be regarded as a radical cure. He asked whether the radiologist could produce by his means the same result as the surgeon did. If he could, what was his evidence? An authority should cystoscope to ascertain the condition of the bladder before treatment, a renal function test should be carried out both before and after treatment, and it should be determined how much residual urine was present in the bladder before treatment, and again after that had been carried out. Sometimes the radiologist said the symptoms to a great extent disappeared after irradiation, but rectal examination showed that the prostate was still enlarged. Symptoms associated with an enlarged prostate were not entirely confined to the urinary organs. Cases which had been treated by X rays and had afterwards come to him for surgical measures had been complicated by (1) retention of urine, (2) by cystitis. Mottram had shown that after the application of X rays mucous membrane revealed definite degenerative changes, and his own experience confirmed the fact that degenerative changes followed inflammatory ones. Another complication was cystitis. The bladder mucous membrane was devitalised by the rays, and so was an easy prey to infective processes. The mere removal of prostatic obstruction was only half the treatment; the other half consisted in dealing with the changes in bladder and kidneys. In malignant disease of prostate he thought the only chance of eradication of the disease was by means of surgery, as in other organs of the body. He had been experimenting recently with a new electrical instrument on the lines of the cautery punch of Young, and his treatment of enlarged prostate by this means had been disappointing. In about 1 per cent. of prostate cases diathermy was of value—namely, those in which post-prostatectomy obstruction had taken place.

Prof. A. FULLERTON (Belfast) spoke of a case of carcinoma of the rectum in a woman, aged 36, who had deep X ray therapy applied by Dr. Morton two and a half years ago, and was now perfectly well with nothing remaining but a scar. One man with a large hard prostate had two doses of rays, and after the second he died; the speaker asked why such deaths occurred after deep therapy. He had tried radium tubes for papilloma of the bladder, but there was little radium in Belfast, and by the time the emanation reached him it was much reduced in strength. For these cases of papilloma he thought diathermy was the best method to date. For malignant disease of the bladder he did a large operation, removing a large slice of the viscus—even if the growth was small—and taking away the lymphatics.

Mr. FRANK KIDD said he agreed with Moynihan that cancer was a local disease. In adenoma of the prostate the results of prostatectomy were so good that it was for the radiologists to present accurate data concerning large numbers of cases treated by their methods for purposes of comparison, and in order that the profession could assess the value of their contentions. There

should also be a systematic following-up of cases and a comparison of after-histories. This was especially necessary in regard to cases treated by deep X ray therapy. In six cases of carcinoma of prostate so treated the result had been absolutely nil, although at first there seemed to be improvement, the prostate appearing to be smaller and softer. But he could not convince himself that the patient would live longer than if it had not been applied. He described a number of cases. He had only selected for X ray treatment cases of carcinoma of the bladder which he considered quite inoperable by surgical means. In one such case the man thought he had been cured by the rays, but examination showed he was still passing blood, and skiagrams showed that the growth had divided into two and gave more comfort for that reason. After two or three applications the X rays seemed to lose their power over the growth. It seemed that the irradiation knocked out certain cells, but the tumour then developed a type of cell which was unharmed by the rays. He was sure he had seen cases in which X ray applications had stimulated the enlargement, so that when the patient presented himself for operation he was in a very serious condition.

CHELSEA CLINICAL SOCIETY.

Exhibition of Cases.

A MEETING of this Society was held on Jan. 20th, with Dr. GORDON LANE, the President, in the chair. The evening was largely occupied with the demonstration of clinical cases.

Dr. A. FEILING showed two boys with marked signs of pseudo-hypertrophic muscular paralysis.

Mr. LAWRENCE ABEL showed a boy who possessed osteomata on the phalanx of one of the fingers and on the metacarpal of the thumb. He considered that they had been always bony. He showed a case of osteomyelitis, and one of osteogenesis imperfecta associated with multiple fractures. He also showed a case illustrating the advantage of avoiding the lacrymal apparatus in resection of the upper jaw for malignant disease; and a man with osteo-arthritis of the sternoclavicular joints and of one hip.

Mr. A. R. THOMPSON showed a girl with bilateral renal calculi and evidence of stunted growth, associated with the renal trouble; also two men who had had the penis amputated for epithelioma, in one case four years ago and in another case five years ago. One of the patients had become the father of a child since the operation.

Mr. IVOR BACK showed an interesting case of dermoid of the floor of the mouth, and also a specimen of sarcoma of the fibula. This was a very rare condition.

The PRESIDENT showed a case of blackening and hypertrophy of the nails of the hands and to a less extent of the feet, which he suggested might be due to a psychic influence, as the patient gave an interesting account of a most gruesome occurrence during the late war.

Dr. ERNEST YOUNG gave an admirable demonstration of his duodenal tube, which had been of much service in cases of gastric trouble, and could also be used for medicaments and food, distributed to the duodenum without the intervention of the stomach. —The paper was discussed by Dr. G. H. HUNT.

Dr. J. D. ROLLESTON gave an account of a case of erythema infectiosum, which he illustrated with photographs. He suggested the name of "Fifth Disease" for it, thus carrying on the name of Fourth Disease, of which he said there were undoubted examples. He suggested that there might be epidemic conditions of the disease, but so far it had not occurred in epidemic form in England.

Reviews and Notices of Books.

A GLASGOW MANUAL OF OBSTETRICS.

By SAMUEL J. CAMERON, M.B., F.R.F.P. & S. Glasg., Lecturer in Clinical Obstetrics, University of Glasgow; ARCHIBALD N. MCLELLAN, M.B., L.M., Assistant to Regius Professor of Midwifery, University of Glasgow; ROBERT A. LENNIE, M.B., Assistant Obstetric Surgeon to the Glasgow Royal Maternity and Women's Hospital; and JOHN HEWITT, M.B., Assistant Obstetric Surgeon to the Glasgow Royal Maternity and Women's Hospital. London: Edward Arnold and Co. 1924. Pp. 573. 21s.

A TEXT-BOOK emanating from a group of men working at the same special hospital is always of interest, especially if the distinctive features of a certain school of thought and practice are exemplified. Dr. Cameron, in collaboration with three of his colleagues at the Glasgow Maternity Hospital, has written this book as a companion volume to his "Manual of Gynaecology." Glasgow is a city notorious for the prevalence of rickets and associated obstetrical difficulties; the experience gained by those attached to a teaching hospital there must be unusually varied, and the fruits thereof as here set out are likely to be of great value to students and practitioners. The book is essentially practical in character, while containing, except perhaps for the section on embryology, sufficient theory to fulfil the requirements of the student for an examination of the standard of the Final M.B. The subject-matter is lucidly expressed, and follows, for the most part, the accepted lines, whilst attention is paid to recent researches and their comparative value discussed. In the section dealing with toxæmias of pregnancy an excellent account is given of the various biochemical methods of clinical investigation, including a short description of the different tests of hepatic and renal function. In the section dealing with post-partum hæmorrhage attention is drawn to the value of modern methods of combating shock; an account is given of the technique employed in blood transfusion and also in the preliminary grouping of the donor's blood. There are useful chapters on the treatment of contracted pelvis, injuries and disease of the newborn, and the causes of stillbirth and neonatal death.

On p. 61, where the statement is made "that inability to touch the promontory with the middle finger denotes that the conjugate is normal," no mention is made of the difficulty in palpating the promontory in a generally contracted pelvis. Again, on p. 538, where Watson's method of inducing labour by quinine and pituitary is described, no word of warning is given that the pituitary must be discontinued should labour supervene before the series of injections have been completed.

The book, without being exhaustive, appears to contain all that is necessary for the needs of ordinary practice. It is clearly printed in large type and excellently illustrated by well-executed and original drawings.

PYE'S SURGICAL HANDICRAFT.

Ninth edition. Edited and largely rewritten by W. H. CLAYTON-GREENE, C.B.E., M.B., F.R.C.S. Eng., Surgeon to St. Mary's Hospital; Lecturer on Surgery in the Medical School. Bristol: John Wright and Sons. 1924. Pp. 619. 21s.

IF, in the surgery of the present day, there is one thing more striking than the widening of its outlook, it is the decline in handicraft of those who practise it. The very facility with which operations can now be performed under modern conditions of asepsis and anaesthesia have made of less importance the manual dexterity of the surgeon, or rather they have obscured the supreme value which must always attach to perfect

surgical technique. Without that technique it is perfectly true that a surgeon's patients may survive his attack, but they will be deprived of at least half the advantage which the progress of surgical science has rendered available.

The first edition of "Pye's Surgical Handicraft" appeared in 1884, and for 40 years it has held a unique position in surgical literature. To generation after generation of house surgeons it has been a friend in need, and in all its nine editions it has steadily kept abreast of surgical progress. The present volume, edited and largely rewritten by Mr. Clayton-Greene, well maintains the great record of its predecessors. Whilst still keeping the many valuable details to be found in the earlier works it finds room for elaborate and precise directions for the most modern methods of blood transfusion, for the diagnosis and treatment of syphilis, and for innumerable other details which would astonish its first author. No attempt is made to describe every method, but in each instance some well-tried and established technique is described in such detail that it should present no difficulty even to the novice. The series of articles on fractures strike us as being especially good and of particular value to many besides the embryo surgeon. But, indeed, there is scarcely a page in the book from which even the experienced surgeon may not gain some hint towards the perfection of his art. Personally, we should be glad to see the day when surgical handicraft formed a definite and important portion of every qualifying examination. We only wish that chirurgery might have remained more true to the great ideal expressed by Walter Pye in the preface of the first edition of his work, that it had held more closely to its etymology *χειρ έργον*, and that its devotees held in higher regard the pure craftsmanship of their profession.

To every student, unqualified or qualified, young or old, we would most earnestly recommend a careful study of this epitome of his craft.

ANÆMIA: ITS CAUSES AND MODERN TREATMENT.

Second edition. By ARTHUR W. FULLER, M.D. Edin. London: H. K. Lewis and Co., Ltd. 1924. Pp. 138. 6s.

THOUGH the title of this book is simple, the subject is a difficult one. It is no small matter to take a common symptom such as anæmia and in the compass of some 120 pages to explain its causes and its treatment. Treatment especially is difficult, for to treat the symptom we must describe the treatment of all the diseases that cause that symptom. For this reason the book cannot be considered in any sense a complete record of what we know of anæmia; it can only be looked on as a pleasant chat on the subject with many useful hints which the wide experience of the writer has taught him. What we believe he has in his mind and wants to tell us is that, where we get difficult indefinite cases, a blood count should be made, for we may get much help from it. The standard he suggests, of blood counts in all cases, will hardly be reached even though it may be recognised that a blood count occasionally gives unexpected and helpful results. It seems a pity to have added an incongruous chapter on neurasthenia to a book otherwise devoted to anæmia.

DISEASES OF THE KIDNEY AND URETER.

Die Chirurgischen Erkrankungen der Nieren und Harnleiter. By Prof. Dr. MAX ZANDEK. Berlin: Julius Springer. 1924. Pp. 254. 12 gold marks.

THIS text-book of diseases of the kidney and ureter gives, on the whole, a straightforward account of such affections, agreeing with generally accepted teaching. It is interesting to note that the author gets good results in certain cases of acute pyelitis by leaving a ureteric catheter in situ, and treats others by decapsulation and scarification of the kidney. He also

recommends neosalvarsan on occasion for chronic pyelitis. He advises against the cauterisation of the vesical opening of the ureter to facilitate the passage of ureteric stones, on the grounds that the sphincter at the lower end of the ureter is thereby destroyed and a stricture may supervene.

The book has some defects. There is no mention of the valuable method of reaching the lower ends of the ureters by median sub-umbilical incision. There is also a certain lack of that detailed information which one expects in a treatise on a limited part of surgery. Thus there is no guide given as to how long expectant treatment in ureteric calculus is advisable or justifiable; no rule is laid down as to what degree of delay in the excretion of indigo-carmin is to be regarded as pathological, to mention but two illustrative examples. Omissions of a similar kind would be easy to rectify in subsequent editions, as revision would speedily detect them.

ESSENTIALS OF PRESCRIPTION WRITING.

Third edition, revised. By CARY EGGLESTON, M.D., Assistant Professor of Pharmacology, Cornell University Medical College, New York City. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 146. 7s. 6d.

THIS is a useful little book, somewhat expensive for its size and contents, and, as is generally the case with American pharmaceutical books, not altogether adapted to English terms and measures. Here its weakness ends; the concise Latin grammar, which explains the recognised prescription terms and structure, is excellent. The construction of the prescription is explained without any of the facts and fancies which betoken the theorist rather than the practising physician, and the conversion of one system of measures to the other is made as simple as possible. Many interesting points are noted with regard to incompatibility and the way drugs should be administered.

JOURNALS.

JOURNAL OF INDUSTRIAL HYGIENE.—In the issue of November, 1924, the question as to whether counter-shock is of use as a method of resuscitation following electrocution is discussed by A. Campbell and L. Hill. They experimented with cats, but found that counter-shock methods proved useless. They conclude that the cause of death in electrocution is ventricular fibrillation, and that the only method of resuscitation which can be usefully employed by a layman is Schäfer's method of artificial respiration. —An investigation into fatigue in the washing departments of steam laundries is reported by M. R. Mayers, who subjected the operatives to careful clinical examination. The work carried out was heavy, for which only the strongest are fit; those with least capacity drop the work and, of course, would not be found employed when the medical inspection took place. Certain definite symptoms of cardiac strain were detected, such as abnormally high blood pressure and pulse-rate, with some cardiac hypertrophy. The signs were least prevalent in laundries of the better type. The author concludes that washing departments of all but the very best laundries are definitely injurious to health, throwing a strain on the vascular system as a whole. She points out that the method of examination employed has general applicability to other industries where muscular work is heavy and the hours are long.—H. M. Vernon and T. Bedford report upon a preliminary investigation of atmospheric conditions in coal-mines. Their observations are based upon kata-thermometer readings taken in the workings at different temperatures and air velocities. They found places where the air was stagnant with conditions adverse to efficiency. The inquiry is one of considerable interest and the need for its

extension is clear; further observations are to be undertaken.—The scheme of medical care for natives on the gold mines of the Witwatersrand is described by L. E. Hertslet. The natives undergo a careful examination before they are engaged, their housing and dietary are under supervision, while medical treatment is supplied when they are sick or sustain accidents. Accurate records are kept; hence the results of the work can be estimated. A fall in the total death-rates from 24.4 in 1913 to 14.5 in 1923 is eloquent testimony to the success achieved; of this gain a fall of 8.8 is due to deaths from disease and 1.1 to deaths from accident. Among the diseases the death-rate from pulmonary tuberculosis has fallen from 3.2 to 1.9, and that from pneumonia from 7.5 to 2.7. The money thus spent in attention to the well-being of the native labour is an economy, as well as a benefit to the natives and the white community.—In the issue of December, 1924, is a monograph dealing with the hygienic significance of nickel which occupies practically the whole of this issue. Its authors are K. R. Drinker, L. T. Fairhall, G. B. Ray, and C. K. Drinker. The first part consists of an exhaustive review of previous work relating to the physiological and toxicological properties of nickel. No such valuable summary has before been published; it includes a bibliography containing 100 references. The main conclusion to be drawn from this review is that nickel as an ingredient of cooking utensils is harmless. The position, however, is far different when nickel gains access to the body in gaseous form as nickel carbonyl, of which there is risk during the manufacture of the metal. This gas is toxic, and fatal cases have occurred. But no such danger is attached to the domestic use of the metal. The second part deals with the detection and estimation of minute amounts of nickel in organic material. Here the authors favour a colorimetric method based on the reaction of nickel with potassium di-thio-oxalate, which they consider can be used with greater facility and accuracy than older methods described in literature. The third part consists of observations on the elimination of nickel ingested with food cooked in nickel containers. Three families were observed whose kitchens were equipped throughout with nickel utensils, so that all cooking and food handling was done with nickel. The experiment lasted for three months. The nickel was corroded to some degree during the cooking operations, but probably less than would have been the case with tin or aluminium. The metal was detected in the urine of those observed, but the amount was too low to be a possible source of kidney damage. No symptoms of any kind resulted.

Reports and Analytical Records.

"VULPRO" WATERPROOF SHEETING.

(MANUFACTURED BY VULTEX PRODUCTS, LTD., GENERAL BUILDINGS, ALDWYCH, LONDON, W.C. 2.)

THIS is a sheeting of a fine texture, dull cream in colour and coated with a preparation containing rubber. It weighs 20 g. per square foot, which is equivalent to 6½ oz. per square yard. Portions were submitted to the following tests and then compared with the original material:—

	Result.
Dry heat at 100° C.	No change.
Steam heat at 100° C.	"
Boiling with soap and sodium carbonate . .	Fabric not quite so plastic.
Contact with faeces and urine for 24 hours at blood heat	No change.
Contact with lysol	"

These results may be regarded as very satisfactory. A microscopical examination showed that the fabric was evenly woven and uniformly covered with the waterproofing medium. The material itself is water-

proof. Its lightness and its tendency not to form creases, with consequent cracking when folded, render this sheeting well adapted for a variety of purposes.

SACRATINTA (SACRAMENTAL WINE).

(SACRATINTA, LTD., 20, SUFFOLK-STREET, PALL MALL, S.W. 1.)

When this wine was analysed the following results were obtained:—

Alcohol by volume	15.56 per cent.
Total solids extractives, not including mineral matter . .	21.6 " "
Ash	0.5 " "
Total acidity as tartaric acid . .	0.6 " "
Volatile acidity as acetic acid . .	0.08 " "
Sugar	20.5 " "

The preservatives sulphites, borates, salicylates, and formalin were tested for, but found to be absent.

This is a wine of a full-bodied and sweet character, and is no doubt well adapted for its somewhat special requirements. The analysis is in fairly close accord with one we made formerly (THE LANCET, March 28th, 1908).

New Inventions.

A COMBINED UROLOGICAL SYRINGE.

THE apparatus shown in the illustration consists of a 10 c.cm. metal syringe and a 2 c.cm. glass Record syringe. The nozzle of each has a cone-joint with external bayonet fitting to which any of the accessories can be attached. If required, a 10 c.cm. glass Record syringe can also be supplied. (c) and (D) are straight and curved adaptors for fitting interchangeable needles. The syringe can then be used for local

anaesthesia or for accurate hypodermic, intramuscular, and intravenous injections. (E) is a nozzle for injecting the anterior urethra and (F) a small metal catheter for injecting the posterior urethra. (G) is employed for injecting fluids through the ureteral catheter into the pelvis of the kidney. When attached to the syringe this is carried out by manual pressure. But for those who prefer to do this by gravity, the part (H), consisting of two metal ends connected by a variable length of rubber tubing, is supplied. The piston of the syringe being removed, the barrel of the syringe is used as a burette. One end of (H) being attached to the nozzle of the barrel, the other to the part (G), by varying the length of the tubing the barrel may be placed at any desired height. (K) consists of two spinal needles and a cannula. It can be used for lumbar puncture, and for spinal anaesthesia by attaching the syringe (B) to the cannula. (J) is used for the instillation of some fluid into the bladder after the completion of a cystoscopy. Such a syringe can be used for urethral injections, instillations into the bladder, pyelography, intravenous and hypodermic injections, and local and spinal anaes-

thetia. It has been designed largely for urological work, but with slight modification it can be adapted to any branch of surgery. All the parts can be boiled. It is of the greatest importance to have accurately-fitting joints, and the best workmanship is essential. The initial cost is somewhat high for a syringe, but, as only one syringe will be required, it means in the end a great saving. Since it will be in more or less constant use, it is not put aside and forgotten until the parts have become rusty and out of action. There is also the advantage that all the parts are in one box; and the surgeon should never find himself in the position of being without an important syringe when operating away from home.

The apparatus has been made for me by Messrs. Mayer and Phelps, Chiron House, New Cavendish-street, London, W.

Cardiff.

T. E. HAMMOND, F.R.C.S. Eng.

SIR JAMES MACKENZIE: THE LATER PHASES OF HIS WORK.

By R. McNAIR WILSON, M.D.

THE wider significance of Mackenzie's work, as is indicated in the memoir published in THE LANCET last week, may not yet have found full expression. His ideas were very simple and thus were apt to be overlooked. His fundamental departure from previous teaching lay not in the realm of cardiology but in that of physiology. It may perhaps be expressed by means of an illustration, dangerous as this method admittedly is. "Suppose," he once said to the writer, "that a man struck you a blow, two things might happen: (1) you might fall down unconscious or dead, (2) you might, on receiving the blow, react to it and fight the aggressor. In the first instance the 'symptoms' presented would be slowing of the pulse, pallor, and unconsciousness, complete muscular weakness, and so forth; in the second instance they would be quickened pulse, flushing, increased acuity of the wits, and increased muscular weakness. Both sets of symptoms may be described as arising from the same cause. But such a description is misleading. The truth is that the blow has produced in both cases the same effects. It has slowed the heart, emptied the cutaneous vessels, weakened the muscles. But, whereas in the first instance reaction has not occurred to these effects—which thus remain evident, in the second case reaction has occurred instantaneously and the whole clinical picture is changed."

It appeared to Mackenzie to follow from this that stimuli are lethal in their essence, and that, were the body bereft of the power of reaction, every stimulus—light, sound, tactile stimuli, and so forth—would necessarily cause death. The heart would "stand still" as a result of any of them. Thus he was led to investigate the nature and meaning of reaction as the real key to symptomatology—this word, reaction, being used in a special sense. For example, a quick pulse may be an expression of reaction to a cause primarily tending to slow down or stop the heart.

He saw that stimuli—the "blows" of life—must determine the degree and nature of the reactions made to them. Thus any circumstances increasing the strength or effectiveness of stimuli must render necessary more active reactions in response to them. This conception led him to include in his survey the organs of special sense—the receptors of stimuli of all sorts, the organs of transmission—the nervous system generally, and finally the organs receiving the stimuli—the heart, liver, stomach, muscles, and so forth. For example, if a stimulus, a slap, is applied to the uninjured skin the response or reaction may be no more than a slight quickening of the pulse; but if the same slap is given to an area of skin rendered hyperæsthetic by injury, the response may be violent with great cardiac acceleration and muscular activity.

Thus the condition of the special senses has a most important bearing on the heart's action and responses. The child sickening for measles, with photophobia is intensely sensitive to light and may develop a very rapid pulse as a consequence of exposure to it. The same light would not influence the cardiac rate in the same child when well. Further—and Mackenzie never lost sight of this fact—a high degree of sensory excitability may so exaggerate a stimulus as to make reaction impossible altogether. Thus a slap on a raw area of the skin may result in the immediate "fainting" of the recipient with strong cardiac inhibition, muscular weakness, and so forth.

Consequently the condition of the sense organs must, he saw, have an important bearing on every case of functional cardiac trouble, and indeed of functional trouble of any organ.

Exactly the same reasoning was applied to the nervous system, which conducts the stimuli to the organs. Drugs and toxins acting on the nerves or centres modify the nature of stimuli passing along or through these. The alcoholic is a case in point: another case is the victim of a toxæmia. Such modified stimuli demand different kinds of reactions or responses from normal stimuli, and so give rise to different kinds of "symptoms." Thus a symptom is a modified reaction, and from a study of it the nature of the modification may be inferred.

It will be seen that this view was widely different from that of the specialist whose interest centres in the heart muscle, in valves, or even in the cardiac innervation. Organic disease, indeed, seemed to Mackenzie, in his later years, to be a relatively small matter; one, merely, of many possible reasons why reaction was changed or rendered excessive or incomplete or prevented altogether.

His study of stimulation and of stimuli and of the reactions made to them brought him, in the last year of his life, to ask himself the question: What is the nature of the impulse which flows along the nerves to the organs and evokes their responses? Prolonged meditation and observation led him to think that it must differ widely from any of the electrical stimuli used by experimental workers to imitate or replace it. For these electrical stimuli produce, as is known, "all or nothing" responses in organs, whereas the natural impulses produced graded responses of an almost infinite variety. He, therefore, postulated a "vital force"—returning, in this, to an old and apparently discredited view—and began an attack on the very fundamentals of experimental physiology.

It would be idle to pretend that physiologists took him seriously or that even his own disciples were ready to agree with him. His challenge, however, had a substantial foundation and will be assuredly taken up.

Mackenzie changed his views about heart disease and disease generally as new knowledge came to him. Ten years ago he spoke always about the myocardium, which he regarded then as the key to the study of heart affections. His early work on arrhythmias was interpreted by him from this point of view. In his last years the myocardium had become for him but a factor in the general process of reaction. His interest had left the heart and was centred in the much larger question of the reception and conduction of stimuli and the organic responses made to them. Great numbers of other workers cultivated the field of his early pioneering activities and reaped a harvest of results—the discovery and identification of auricular fibrillation by Sir Thomas Lewis is a case in point. But these researches in no sense invalidated any of Mackenzie's discoveries. They merely fulfilled them. On his last great enterprise, which again arose naturally out of his first labour, he journeyed practically alone. The academic—using that word in no unkind sense—simply did not know what he was talking about, and often frankly told him so. Again and again he was advised to confine himself to his "own subject." He expected this and was never dismayed by it. General practitioners, on the other hand, usually understood him at once because their daily problems were presented to them in a new light.

Extract from a Report on the use of

DIMOL SNUFF

in the treatment of

Common Colds

by a Nose and Throat Specialist of over 30 years' experience.

"The discomforts of nasal catarrh are known to everybody, especially in the fluctuating temperatures of an English winter, but there is no reason why any type of this common ailment should not be dealt with promptly and

- (1) Aborted in its incipient stages,
- (2) Ameliorated in its active stages, and
- (3) Quickly cured

with the aid of Dimol Insufflation Powder, used as a Snuff.

"The simplest and most effective method is to tumble a little of the powder from the glass container, in which it is sold, on to the back of the closed left hand in the little hollow between the fore and middle finger knuckles, and inhale vigorously into each nostril. It gives immediate relief to the congested lining membrane, thins the heavy viscid discharge, and clears the nose and frontal sinuses of the dull aching always accompanying a severe 'head' cold.

"The Snuff should be taken every hour during the acute stage of the catarrh, and every two or three hours when the symptoms have abated.

"The latest Public Health reports on the present mixed infection of the nose and throat clearly indicate the use of this powerful bactericidal powder.

"Dimol Snuff is an extremely fine powder of high antiseptic and bactericidal power; it is guaranteed by the manufacturers to have a Rideal-Walker Co-efficient equivalent to 20 per cent. pure carbolic acid, and to be free from all deleterious action on the mucosa.

"The Snuff, taken three or four times a day during an epidemic of influenza, should be a perfect and pleasant preventive to the insidious settlement of the pervading bacillus in the nose and throat."

In bottles at 1/6 each, and in tubes at 6d. each.

MEDICINE IN PARLIAMENT.

THE House of Commons meets again after the Christmas adjournment on Feb. 10th, to begin the duties of a session which may be an unusually calm one, but which may be speedily interrupted by certain waves of political feeling which have already appeared on the surface. In this House of Commons there will sit as large a number of qualified medical men as have ever sat there, and they represent various shades of political thought, being drawn from all parts of the British Isles and from all ranks of medicine, professional, official, and academic. They will, therefore, be recognised in the House of Commons, as they should be, not merely as standing for a sectional interest, but as able and willing to speak from knowledge and experience on the wide issues of public and personal health, in which an increasing number of their colleagues are taking interest. And some of these issues should speedily come to the front, so that the faces of the medical Members should shortly be familiar to Mr. Speaker, who has always recognised with great courtesy the right of the representatives of medical science to take part in discussion involving medical matters. We print on another page the portraits of these representatives.

We commend now to the consideration of medical Members of the House of Commons the need for early action in regard to the sale of patent medicines. Such action is in the best interest of the community, and will be dictated by no narrow professionalism. Unless something is done to stem the continued supply of remedies which are no remedies, boosted by assertions which have no basis in fact, it will be difficult for any scientific measure dealing with health, whether of public or personal application, to have its fair and right effect. The evil is perfectly well recognised: only the most regrettable chance prevented an appropriate sequel to the Report of the Select Committee on Patent Remedies, which was rendered in 1914, and there is no need whatever to go over the whole ground again of inquiry, for convictions which were then reached remain unchanged or have been more widely confirmed. One little measure, favoured by everybody, ought to pass the quicker. The Therapeutic Substances Bill, which seeks to standardise the quality of vaccines, serums, and other substances such as salvarsan, insulin, and pituitary, by regulating the manufacture and sale of them under licence, has since been introduced in the House of Lords where it was given a third reading. At present stuff which the United States or France or Denmark rejects as not good enough for them is good enough to be dumped on us. And other legislative measures which should fairly command attention came up at the important interview between the Minister of Health and an influential deputation from

the Peoples' League of Health on Jan. 27th. This deputation was the aftermath of an International Health Conference held in May of last year at the Wembley Exhibition, when two sessions were devoted to the consideration of legislative reform with regard to health matters, and a series of resolutions were moved.¹ Mr. NEVILLE CHAMBERLAIN assured the deputation that he was prepared to accept generally the recommendations of the Food Preservatives Committee, which would shortly be circulated in draft. He was proposing to consolidate the existing legislation as to food and drugs, but in the meantime to carry out many recommendations which could be done without delay. A day or two ago, in reply to a deputation from the London Chamber of Commerce, which suggested that no evidence had been produced to show any actual prejudice to public health from preservatives in food, Mr. NEVILLE CHAMBERLAIN insisted on the possibly cumulative effect of consuming many kinds of food containing preservatives, and the important fact that some sections of the trade were now getting along without preservatives at all. He foreshadowed an amending Public Health Bill which would give local authorities much needed powers to remove tuberculous cases which were proving centres of infection, especially to children. Most important of all, he stated the Government's intention to reform the Poor-law as soon as possible. The delay in dealing drastically with the available hospital bed supply of the country has paralysed largely the abundant efforts made by so many parties to render hospital treatment available and effective to the whole of the community.

These matters are so far-reaching that in comparison with them many important proposals may have to wait; but these other measures should not be lost sight of. An agreed Bill was available last session so to modify death certification that no registration of death should take place unless and until the registrar has received a medical certificate, first of the fact of death, and secondly of the cause of death. The Factories Bill, which was read a first time last Parliament, to consolidate and amend enactments relating to factories, contained much that was needful in order to bring the factory life within the purview of the public health system in the country. The new knowledge of ventilating and lighting principles must in fairness be applied to all sections of the industrial population, not excepting those who are doing clerical work. No doubt the Bill as it stands will be represented as a crushing handicap on struggling manufacturers, and to obtain any measure of consolidation it may be necessary to compromise over cubic air-space. No medical man or woman, least of all those who are actually in Parliament, will imagine that legislative changes are going to have a great effect unless the people of the country are roused to a sense of the importance of obeying the laws of hygiene. A commendation made at the Wembley Health Conference by Miss MARGARET BONDFIELD, then a Member of the Labour Government, remains valid, that voluntary workers who have the time to talk about health matters can render great service by removing the issues from the area of crankdom. And this should be all the easier now that there is a clear vista of possible health legislation in the immediate future. Those who represent medicine in Parliament can deal worthily with the great responsibilities likely to fall upon them, and their views will be appreciated by the House of Commons.

PROGNOSIS IN CHRONIC DISEASE.

IT IS a curious fact in practical medicine that the doctor is valued by the laity as much for his power of prophecy as for his skill in healing. A sick man wants to be well, but he wants as much or more to know whether he is going to get well or not. In acute illness the doctor's great function is to assume the responsibility, in normal circumstances belonging to the patient, for deciding the course of life, and the nurse's part is to take responsibility for ordering its minute details, while the patient's share is to yield all his will to these guardians and be "a good patient." In chronic sickness the patient asks for assurance about what is to come almost as much as for immediate relief; here in particular he needs someone else to take the burden of his future. With the progress of hygiene and good living the proportion of creaking doors in the population has much increased; instead of dying by the means which are "natural" when his tissues begin to decay, modern man is disappointed if he cannot live twice as long as his primeval ancestors. Add to this the rise in the demanded standard of "feeling well," which has naturally followed the general increase in healthiness, and it is easy to understand why the patient is so anxious to know whether he will get well, and if not when may he expect to die; and if the answer is that he may anticipate a partial restoration to health, how well he may expect to be and when.

As Dr. M. O. RAVEN points out on another page, in acute and subacute diseases, where the whole history is easily grasped in one view, prognosis is relatively simple and has reached a standard which is for the moment not unsatisfactory; and whether the outlook is good or bad its comparative certainty alleviates much human misery. The certainty of death in inoperable cancer is in its way as helpful a piece of knowledge as the certainty of recovery in chicken-pox, and the wretchedness of a migraine or an acute lumbago would certainly not be taken in the light-hearted way in which they are commonly received, were the sufferers not fully assured from their own or their friends' experience that a few hours or days would see an end of their pain and be succeeded by a period of almost certain immunity from another attack. But in a great number of disease processes, often very ill-defined in their early stages, prognosis remains more dubious and speculative than it should be. As consequential events become more widely separated in time, so it becomes more and more difficult for the human mind to apprehend that there is a connexion between them. Man has long since passed the stage when he discovered that the sowing of a seed was causally related to the springing of a plant, but there are still considerable difficulties in viewing the facts of 20 or 30 years of slight and slowly progressing ill-health as a whole; the past is dim and not very clearly remembered, the best of notes cannot be complete, and a host of similar processes have intervened and obscured the view. Patients move about and change their doctors, and

our centres of medical research have the most inadequate methods for finding out what ultimately happens to the patients who pass through the wards; and here it may be interjected the follow-up systems of some American hospitals deserve study, for it is surely possible to reach, for other diseases, some of the success which has accompanied the organised attention paid to tuberculosis. Administrative exigencies seem to have wiped out the high hopes which were entertained of the knowledge which would come from the history of war pensioners. At the moment everyone will be thinking of the shining example set by JAMES MACKENZIE; that there is a fruitful road which can be travelled he showed plainly enough, but there is no doubt that it is a rough path and requires grit and genius, if it is to be pursued to any definite end.

If, then, there are singularly few facts on which the prognosis of chronic disease can be based, are there any general principles which may be helpful till more definite data are available? Dr. RAVEN indicates one which seems to rest on a good basis. Disease is a process, not a state, and it must therefore progress in one direction or another. The natural history of the acute infectious diseases is so well known that, in defiance of Mr. YULE, a typical course for the rise, fastigium and decline of each of them is defined in the text-books; something is happening all the time. Of thoroughly chronic diseases we can think of two kinds, one in which degenerative processes begin slowly and more or less steadily progress till the economy can no longer compensate for its defects, the other in which with a relatively sudden onset a substantial degree of illness is reached which proceeds slowly and gradually to complete or partial cure. The rules which summarise the history of these cases are no doubt discoverable; and are possibly as precise as those which enable prognosis of acute conditions to be as good as it is. And it seems more or less obvious that the whole duration of the processes must be proportional to the rates at which they are proceeding at any time. What the proportion is we do not know, for we do not know the rules which these rates of change follow. The progressive destruction of the liver in cirrhosis may likely be expressed graphically by a straight line with some deviation due to compensatory overgrowth; the healing of a periostitis more probably follows a logarithmic curve, rapid at first and becoming slower and slower as the restoration to normal is approached. But it seems evident that for a first trial a measurement of the time in which a just perceptible change takes place gives some sort of gauge of the time which will be occupied by the whole. In any case the establishment of the fact of change indicates active advance or retreat, as was elegantly illustrated by DREYER when he pointed out that variations from day to day in the agglutinin titre of the blood would distinguish a genuine case of enteric infection from some similar pyrexia in a man who, in consequence of antityphoid inoculation, gave a positive Widal test but without any material changes in titre over a week or more. Similarly, the absence of perceptible change over a period of months or years must signify that for practical purposes the advance or retrogression of the process has gone as far as it means to. It seems as if it is along some such lines as these that data could be obtained from which the mathematicians might ultimately tell us how chronic disease goes along. But it is no simple matter.

THE TREATMENT OF PULPLESS TEETH.

TECHNIQUE in treating pulpless teeth, though primarily the concern of the dental profession, is also of interest to the medical practitioner, who may be witness of the infection supervening on dental treatment. The broader aspect of pulpless teeth and their possible relation to systemic infection was touched on incidentally only in the interesting paper read by Mr. L. E. CLAREMONT before the Odontological Section of the Royal Society of Medicine on Jan. 26th. Both Mr. CLAREMONT and those who joined in the discussion took up the attitude that while the treatment of pulpless teeth is not always satisfactory, yet there is no valid reason for refusing to treat such teeth under suitable conditions and within definite limitations. The fact that focal infection has assumed so important a place in modern medicine has placed a heavy responsibility on the dentist, but it has not laid an embargo on his treatment of pulpless teeth to the extent of making it a pathological offence to conserve teeth which have no longer a vital pulp. Even taking at its highest value all that has been said in condemnation of dental infection, it is legitimate and, indeed, desirable that the dentist should save rather than extract teeth. But conservation must be attempted after careful consideration of many factors, and should imply a standard of technique which is often lacking at present.

The pulpless tooth may be considered from two points of view. There is the tooth in which the progress of caries has led to an exposure of the pulp. Here treatment involves the extirpation of the pulp and filling the root canal. Secondly, there is the tooth in which the pulp has died as a result of inflammation, and an infected and septic condition of the pulp-root canals has been established, often extending beyond the apex of the tooth into the peri-apical tissue. With regard to the first class, the fact that the pulp is still vital does not of necessity imply that it is free from bacterial contamination, for, as Mr. J. G. TURNER in this country, and HENRICI and HARTZELL in America, have shown, even the pulps of teeth free from caries may contain bacteria. Yet there is every reason to think that any infection is only superficial and has not penetrated into the dentine lining the root canal or beyond the apex. Provided that an adequate technique is employed there is every reason to believe that the pulp can be removed and the canal filled in a way to render it free from infection and reasonably immune to subsequent bacterial invasion. Unfortunately, clinical experience shows that in a certain number of cases infection follows, and may result either in an acute abscess or more commonly in a chronic infection leading to a painless apical rarefaction which may only be discovered if the teeth are radiographed. There are no statistics to show how often this occurs; all that can be said is that it is not uncommon. Although infection via the bloodstream is a possibility, it is much more likely that it is introduced by the operator in the process of extirpating the pulp and filling the root. A knowledge of what may be regarded as the average root canal technique bears out this hypothesis. Indeed, it is not too much to say that it is surprising that infection does not occur more frequently. This sounds like a severe indictment of dental technique, but it does not overstate the case. Aseptic dentistry is an impossibility for many reasons, but a greater degree of antiseptic dentistry is undoubtedly possible. Mr. CLAREMONT outlined a careful method of treating devitalised teeth which though not absolutely proof against failure, would certainly make it much less common. There is no doubt, however, that the standard of root canal treatment has progressively improved during the last decade, and that an increasing number of dentists are adopting methods which are deliberately planned so as to exclude infection during the stages of root canal treatment. In this matter dentistry is much indebted to Mr. J. B. PARFITT, who has elaborated a method which is logical and thorough, and

yet not so exacting as to place it without the scope of the usual conditions under which dentistry is performed. In spite of a certain number of failures, many of which could undoubtedly be prevented by a more scientific technique, there seems no reason to adopt the pessimistic attitude of some who argue that it is unwise to retain in the mouth any tooth which has not a living pulp. A dentist who is aware of the potential dangers of an infected tooth and shapes his treatment accordingly so as to exclude avoidable infection, during the process of treatment, is justified in treating and saving teeth with exposed pulps. It would be a wise precaution, however, to have the teeth radiographed periodically to provide against the contingency of apical infection later, for a pulpless tooth is undoubtedly less resistant than a vital tooth.

The problem of the tooth already pulpless and with infected canals is much more difficult, and there is more to be said for the attitude of those who are so impressed by the difficulties of sterilising the peri-apical tissues that they do not consider it justifiable to subject their patients to the risk of leaving infection behind, the more especially as it is usually painless and may, therefore, give no local signs of its presence. Mr. CLAREMONT took up a guarded attitude on this subject. Provided that certain essential conditions were fulfilled, he thought that it was legitimate to undertake the treatment of such teeth, and that it was often possible to do so with success. Treatment is most likely to be successful on the anterior teeth with single roots. It should only be attempted on teeth which have healthy periodontal membranes and do not show any signs of marked apical infection. A radiograph should precede treatment, and the teeth when filled should be regarded as being on probation and examined at intervals, and, if possible, radiographed. The ideal treatment should logically include cultures from the root canal to ascertain when they were free from infection. Mr. E. C. SPRAWSON, in the discussion which followed, stated that this step is being introduced at the London Hospital Dental School as a routine procedure. This is an admirable innovation, the educational value of which to the student should be considerable. As a practical addition to private practice it is scarcely feasible, for it would add so much to the cost and length of treatment as to make it prohibitive except to a favoured few. It was noteworthy that though the discussion revealed a wide variety of methods of attempting disinfection of septic root canals, there was a very general endorsement of Mr. CLAREMONT's moderate attitude, that though the treatment of infected teeth presents great difficulties and places a great responsibility on the dentist who undertakes it, yet there are cases in which treatment is fully justified and is often completely successful as judged by both clinical and radiographic tests. Indeed, even the presence of apical rarefaction may not be a barrier to successful treatment, for bone regeneration is possible, as was shown by some excellent radiographs exhibited by Mr. CLAREMONT.

To put it shortly: the forceps is not the only way of treating dental sepsis. In many cases extraction is the only possible remedy, but in others it is possible to remove the infection and still leave to the patient the use of his teeth. The amount of attention which is being paid to this aspect of dental surgery leads us to hope that the conservative treatment of dental infection will become increasingly successful.

INDEX TO "THE LANCET," Vol. II., 1924.

THE Index and Title-page to Vol. II., 1924, which was completed with the issue of Dec. 27th, will shortly be published. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

Annotations.

"Ne quid nimis."

THE HUMAN PEDIGREE.¹

DURING the week a new edition has appeared of Sir Arthur Keith's famous book surveying the story of man's pedigree from an infinitely past date as evidence in support of the theories comes up and receives confirmation. The book first appeared ten years ago, and in spite of the fact that at that time the whole world was convulsed with the efforts of modern men to destroy each other, there was a wide recognition that knowledge of the material which was being disintegrated by thousands had the deepest interest for all. In its first form four editions were issued, so that the work has been duly reviewed in these columns; but the latest impression is practically a new book so much has it been revised and enlarged, while during the interval of a decade much has happened which necessitated recasting of material, and, as the author frankly allows, modification or change of opinion. Discoveries have been made in this country, in France and Germany, in the United States, Australia, and Java, and notably in South Africa, which compel an alteration of judgment in regard to many general conceptions, and notably in the estimates of geological time. Again, the popular view of racial emigration has to be altered in view of the belief that such movements played only a minor part in shaping human evolution. Prof. Keith believes that the distribution of modern human racial types, as seen at the dawn of history, cannot be accounted for unless we presume that they have been evolved in or near the regions of the earth which they now occupy or even occupied at the beginning of time, although, with his enormous range of knowledge, we may be certain that he would not disregard evidence which in particular cases cut across the generalisation. In these volumes attention is focused on the prehistoric sites in turn, which means that evidence is examined in series and matters are discussed more or less as they come up for consideration; but a full and explicit index will give the careful reader an opportunity for a systematic examination of the facts and a comprehension of the broad conclusions. A vast amount of detailed information is contained in every chapter, and the clear presentation is well illustrated by the sections which deal with the discovery of the Piltdown skull, and which explain how far fossil fragments can yield reliable evidence in respect of man's evolutionary history. The author half apologises for introducing what he describes as dry technicalities concerning the Piltdown skull, but no chapter better exemplifies than this one the labour, the accuracy, and the conscientiousness which have gone to the making of the big treatise. In this brief notice it is only intended to advise our readers of the intellectual treat which has been provided for them.

RELAPSE IN WASSERMANN REACTION AFTER TREATMENT.

THE failure of mercurial continuation treatment to keep a negative Wassermann negative in syphilitic out-patients has recently been noted by Prof. Ernest Glynn, Dr. R. E. Roberts, and Dr. Phoebe Bigland. Working in connexion with Dr. F. P. Wilson's clinic at the Royal Infirmary they studied the Wassermann relapse incidence in 503 patients whose reaction was negative after the standard admission course of six doses of salvarsan and eight of intramuscular grey oils, and communicated the results to a pathological meeting held at the Liverpool Medical Institution on Jan. 15th. About two-thirds of the 503

patients received continuation courses of either grey oil or mercury tablets—the latter usually prescribed to sailors or other "wanderers"—to keep their W.R. negative. About one-third received no treatment for a few or many months, because of irregular attendance. The authors were therefore able to compare the Wassermann relapse incidence in the three groups. The patients were classified into five periods dating from the beginning of their negative W.R., viz.: 0-6 months, 503 patients; 7-12 months, 382 patients; 13-24 months, 264 patients; 25-36 months, 100 patients; 37-48 months, 27 patients. There were 185 "first" Wassermann relapses among these; six cases of reinfection were excluded. The Wassermann relapses were classified into complete and partial, the technique being No. 4 M.R.C. report. The authors expected to find that patients receiving no treatment relapsed more frequently than those treated. But exactly the opposite occurred, as shown by the following examples:—

Examples of Partial (P.) and Complete (C.) Wassermann Relapse Incidence in 503 Patients.

Period in months.	No treatment.		Grey oil.		Mercury tablet.	
	P.	C.	P.	C.	P.	C.
0-6 and 7-12 combined	9.5	13	28.2	20.3	15.6	13.0
13-24	6.6	9.2	No cases.		12.5	7.8

One hundred and nine of the 185 patients with the "first" Wassermann relapse became negative again on further treatment—usually with salvarsan and grey oil. They were classified in the same manner. Thirty-five relapsed a second time, and in general the incidence of the second relapses in the three groups was the same as that in the first relapses. In both series complete and partial relapses were more frequent after grey oil than after mercury tablets. These unexpected results were not due to the influence either of (a) selection by clinicians; (b) Wassermann on admission; (c) the "delay period"—viz., time elapsing between original infection and patient's arrival at clinic; (d) occasional deviations from standard continuation treatment or other variable factors. P. Fildes and R. J. G. Parnell, unknown to the authors, had independently come to a similar conclusion in 1919 on the failure of mercurial continuation treatment after salvarsan by the study of the Wassermann relapse in 129 syphilitic patients at Haslar; while Sir Patrick Watson, of Edinburgh, 40 years ago did not advise the administration of mercury to prevent the occurrence of the manifestations of syphilis at a later date.

The various factors which might account for these unexpected results were next considered by the collaborators. They held that it was wrong to assume that because mercury is often beneficial in treating active syphilis with a positive W.R., therefore it must be beneficial in latent syphilis with a negative W.R. The pathological conditions were absolutely different. Evidence was produced that the increased Wassermann relapse incidence after mercury might be partly explained by the development of mercury-resistant spirochaetes, sometimes by a provocative reaction, but chiefly, as the statistics suggested, by a lowering of the patient's immunity. This last was more likely to occur if the mercurial continuation courses began, as usually happened, about six to eight weeks after the end of the admission course of salvarsan and grey oil, from which it sometimes took the liver six months to recover. Evidence was next produced that the Wassermann relapses were injurious, partly because the complete relapses were associated with clinical relapses in 6.7 per cent. of the "no treatment" cases, in 9 per cent. of the mercury tablet cases, and in 16.9 per cent. of the grey oil cases. In order to try to prevent the occurrence of Wassermann relapses, it was advised that two or possibly three continuation courses of salvarsan

¹ The Antiquity of Man. Revised edition. By Sir Arthur Keith, M.D., F.R.S. London: Williams and Norgate, Ltd. 1925. Two volumes. With 266 illustrations. Pp. 753. 25s.

should be given during the two years, controlled, if necessary, by the Van den Berg lævulose tolerance and other tests, the first being given about six months after the admission course. The dormant, but inaccessible spirochaetes were more likely to be finally destroyed by the intensive administration of this powerful remedy than by the prolonged courses of mercury, a drug now recognised as much less efficient in the treatment of active syphilis.

TAPE-WORMS AND FLUKES IN EGYPT.

MANY fundamental discoveries in tropical disease, more particularly concerning the life-histories of intestinal parasites which afflict man in Egypt, have emanated from Cairo during the past century. The classical investigations of Looss on *Ankylostoma duodenale* and of Leiper on the schistosomes are still fresh in our memory, and now Dr. M. Khalil, a distinguished pupil of the last-named investigator and a student of the London School of Hygiene and Tropical Medicine, has summarised¹ the recent progress of anthelmintic work in Egypt, for which he himself appears to have supplied the stimulus. Up to 1913 no united efforts had been made to check or treat ankylostome or schistosome infections in Egypt. Ankylostomiasis has probably been endemic in that country since the earliest times, but it was not till 1847 that the infecting worms themselves were discovered in Cairo by Pruner. Recent improvements in the therapeutics of ankylostomiasis, culminating in the discovery of carbon tetrachloride as an anthelmintic, have made it possible to subject the population to "mass treatment" on an extensive scale.

Schistosomiasis, too, has been indigenous in Egypt from the dawn of history, for the eggs of these parasites have been demonstrated in the tissues of ancient Egyptian mummies. The trematodes themselves were discovered by Bilharz in 1852 and their curious life-history was already suspected by Sonsino, who dissected large numbers of the intermediate hosts, fresh-water snails, the elucidation of this problem being finally effected by Leiper in 1915. The world is indebted to Christopherson for the tartar emetic treatment of schistosomiasis which he introduced in 1917 and which is now being used with great effect in Egypt, and it is with this aspect of the subject that a section of Dr. Khalil's report is concerned. We learn that the number of intravenous antimony injections given during a day by a single medical officer sometimes exceeds 400, and so skilled do they become that 150 patients may be injected within an hour. The prosecution of a vigorous ankylostomiasis and schistosomiasis campaign is carried out by the organisation of special camps, or annexes, composed of tents and wooden huts where large numbers of patients are received for examination and treatment. Educational measures are regarded as of special importance, popular propaganda amongst the villagers being carried out by means of leaflets, educational lectures, and particularly by sensational posters. For the prophylaxis of these diseases the coöperation of religious teachers is sought, directed especially against the pollution of water-courses which is an offence condemned by the sayings of the Prophet; village latrines are being established, and the diseases themselves stamped out by mass treatment.

The attempt to exterminate the fresh-water snails may well be successful, for the system of irrigation in Egypt lends itself, during the summer rotation, to the drying up of the smaller irrigation channels where the mollusca soon die when exposed to the sun, while the small amount of water left in the deeper channels can be treated with copper sulphate, which appears to be lethal to these creatures, even in a dilution of 1:4,000,000. The report also includes an interesting

survey of parasitic infections of a single Egyptian village in the Delta; the intensity of parasitism may be judged from a photograph of a fellaheen boy holding a board on which are pinned 81 mature ascaris worms expelled after one dose of 3 gr. of santonin. The report, which is extremely well written, concludes with the description of a new trematode parasite of the rat—*Echinostoma aegyptiacum*—by Khalil and Abaza, and an investigation on the complement-fixation reaction in bilharziasis using an extract of *Fasciola hepatica* as antigen, by A. T. Shousha, who finds that the serum of bilharziasis patients give a positive reaction in 67.6 per cent.

SOME PROBLEMS OF HOSPITAL ADMINISTRATION.

A RECENT number of *The Modern Hospital* (December, 1924) contains an article on Some Fundamental Problems in Hospital Administration, by Dr. E. M. Bluestone, assistant director of the Mount Sinai Hospital, New York, which is calculated to produce hard thinking on the part of those engaged in hospital practice and hospital administration. The writer suggests that many physician-superintendents visualise hospital administration in terms of hotel management, and the larger the hospital the more likely is the necessary differentiation and division of labour to produce this result. A comparison of British and American methods might lead to instructive lessons. The position of a medical superintendent in American hospitals differs in many respects from his position in this country, and even here there is a wide divergence of method—our teaching hospitals for instance, have not the same highly-organised medical administration centred in one person as have our State mental hospitals or Poor-law institutions. But when allowance is made for these differences there is much that is common to all hospital administration wherever it is found. The fear that "paper work," as Dr. Bluestone terms business organisation, may overshadow the clinical aspects of medicine is a real one. Statistical inquiries into everything which concerns the hospital and the patient become more elaborate every year, and inasmuch as the staff cannot, for financial reasons, be correspondingly increased, most hospital officers find themselves involved in a large amount of clerical work. It is difficult to see how this can be avoided in dealing with a system which is continually increasing in complexity, but it is none the less clear that we shall have to be very much on our guard if the human aspect is to be retained. Nothing is easier than a perfunctory filling in of forms and compilation of figures, and generally speaking, each additional form added on to the organisation means that the patient himself gets less attention. Physicians who have to deal with State-aided patients in the tuberculosis departments of hospitals, for instance, know well how real this danger is.

There is, moreover, the ever-present difficulty that the patient is apt to lose his identity and become merely a case, occupying a bed with a number. Dr. Bluestone deals with a firm hand with all examples of this failure to realise that the patient is a sick person and not an inanimate case. He cites as examples from his own personal observation in American hospitals the list of tonsil operations which have to be worked through and are done at times in a perfunctory manner, the difficulty of maintaining interest in the so-called chronic cases in which there is no question of differential diagnosis or hope of treatment, the unnecessary clinical manipulations for purely demonstration purposes, the preparation of patients for the weekly operation list when they are not likely to be dealt with, the discussion of details of illness, especially regarding hopeless prognosis, in the presence of the patient, and lastly short cuts which save time but not the patient's feelings, or which increase operation risks. In all this Dr. Bluestone is at pains to point out that he has no intention of

¹ Ankylostomiasis and Bilharziasis in Egypt. Ministry of the Interior, Egypt, Department of Public Health. Reports of the Public Health Laboratories. No. 6. Government Press, Cairo, 1924. Pp. 196. Price P.T.30.

belittling the work of science which has written so many bright pages in the history of mankind, but that he is anxious rather, as an administrator, to keep the human side of medicine always to the front. He pleads for less of the cold emphasis on quantity production and for a broader interpretation of hospital service, and in conclusion he raises the question whether we are right in herding the sick together in such large institutions. In this last matter he seems to have touched upon a very real and serious question in hospital administration. It is true that a small hospital must have high over-head charges, but it is equally true that a very large hospital may over-emphasise quantity production in the administrator's office, and eliminate the human factor still further.

POSTURE AND REST.

THE distinctive feature of modern industrial practice is the elimination, so far as it can be effected, of heavy manual labour. Great advantage to health and the economics of production comes therefrom. Nevertheless, the time is distant when recourse to human physical effort will be abandoned; it still holds, and must continue to hold, an important place in industries. While, however, much scientific attention has been directed to the laws which govern the use of mechanical power, curiously little thought has been expended on the best methods of employing human power. The latest report¹ of the Industrial Fatigue Research Board is an effort in this direction; it deals with the effects of posture and rest in muscular work and comprises two interesting studies. The first deals with weight carrying, a process of prehistoric antiquity. The investigator, E. M. Bedale, has taken eight ordinary methods in common use and determined the net working metabolism involved in each case. The methods were (1) weights placed on a tray held in front of the body, (2) weights on a tray supported by shoulder straps, (3) equal weights carried in either hand, (4) weights carried on a board on the left shoulder, (5) weights on a tray supported on the left hip, (6) weights placed in a rucksack, (7) weights in pails on a shoulder yoke, (8) weights on a tray upon the head. The loads, which varied from 20 lb. to 60 lb., were carried along the level at an even pace for 100 yards, after which metabolism was ascertained by the Douglas bag method. No attempt was made to determine the maximum load or the mechanical efficiency of the work. The results obtained, which are given in detail, are fully discussed and shown in graphic form; they indicate conspicuously low metabolism costs for yoke-carrying; appeal to ventilation-rate, pulse, and blood-pressure changes show that this method involves less physiological disturbance than any of the others. A critical point, for the individual (a female) observed, was noted at about 40 lb. for the maximum load for rucksack-carrying and tray-carrying, but not until 60 lb. was reached for yoke-carrying; this critical point is important and calls for further extended inquiry, since work becomes more costly in metabolism for heavier loads and is, therefore, economically more expensive. A complex interaction of four disabling factors—local strain, posture, gait, and chest freedom—is concerned in each method, and where these factors are least concerned the method is physiologically least expensive. This investigation suggests that a load should not exceed 35 per cent. of body-weight, but further work in both laboratory and factory is needed before a definite rule can be laid down.

The second section of the report, contributed by Dr. H. M. Vernon, deals with strength of pull, or weight-lifting power, as determined by a dynamometer, the spring balance of which registered up to 500 lb. The handle could be fastened at different heights above the floor level; the power of pull was

found greatest with the handle at 28 inches from the floor, and fell off above and below this height, but below 15 inches it became increasingly greater as floor level was approached. Standing on one leg instead of two only diminished the pull by 2 per cent., while using one hand instead of two nearly halved the pull. Rest pauses of varying duration were introduced; but the total work then done was less than without the rest pauses, so long as the subject remained motionless during the rests; but, if he changed his posture by bending his shoulders or moving his arms, and by so doing influenced his circulation, the total work done was decidedly greater, while no greater acceleration of the pulse occurred. In fact, capacity for work was far more beneficially affected by change of posture during an interval than by the length of the interval. Hence the deduction is drawn that postural changes should be encouraged in industrial work; thus for many processes which can be done equally well sitting or standing, alterations in posture should be the rule; while apparently unnecessary and undesirable movements indulged in by operatives at repetition work may be introduced unconsciously by them in order to promote circulation through fatigued muscles.

THE LIMITS OF MICROSCOPY.

THE labours of professional microscopists in the latter part of the nineteenth century, stimulated and encouraged by the vitality of such bodies as the Royal Microscopical Society, have resulted in production of such simple, cheap, and efficient instruments that no student and no practitioner of medicine has any valid excuse for not possessing one and making practical use of it. Indeed, the microscope has become something of a cult and has been regarded as the end rather than as a means. Possibly "the microscope" is not held in such awe nowadays as it was by the latest Victorians, but there is nevertheless a tendency to look upon it as the last court of appeal. And in medicine this, no doubt, is fairly true. In bacteriology, for example, it is the highest court we have, though it would astound the general public to know how small amount of his time the bacteriologist devotes to microscopical work. But it is the last word in the study of much disease.

But all know that slavish dependence on the microscope has definite dangers. Microscopic technique is not entirely without its difficulties. Even for the simplest procedures a certain amount of training and practice is necessary, while for more advanced work the necessary apprenticeship may well extend into years. For the majority of medical men this apprenticeship is impossible; but they can compensate to some extent for lack of skill in the use of the more complex instrument by learning to employ a simple hand lens. What is commonly lost sight of is that the microscope merely increases the range and power of normal vision. But only to a certain extent. It enables us to distinguish the present biological unit, the cell, but it does not go very much farther than this. If we wish to gain information about the structure of the ultimate, or penultimate, units of matter we must use other methods and other instruments. Sir William Bragg¹ has recently described in language so clear and simple that even the most uninstructed layman cannot fail to understand him, how by the use of the X rays it is possible to study the actual structure of molecules. Our mental vision can, as it were, actually see the smallest body which we can imagine. But this takes us a long way from ordinary medical practice. If having eyes we see not, neither the microscope nor X rays will help us, and for much the same reason that a high ocular merely intensifies the defects of a poor objective. The first duty of a medical man is to train his senses so that, unaided, they may inform him as exactly as possible about

his surroundings. Confronted with any particular problem in diagnosis he should be able to collect all the relevant facts which may be recognisable by his unaided senses. Only if these are insufficient to answer the question should he resort to adventitious aids. And it is as well to realise that the microscope will reveal quite a new range of facts. It may be that the single one which is necessary to solve the problem will be immediately apparent; but it may equally well happen that the new facts will complicate the matter still further.

It is a safe rule in microscopy, as in other things, never to "press." As the expert golfer always drives well within his powers, but can pull out an extra 30 or 40 yards if necessary, so the expert microscopist likes to keep a few magnifications in reserve. Every teacher of histology knows the difficulty of making his students use the lower powers of their microscope. The tyro instinctively starts with the highest powers available; the expert invariably begins with the lowest. As a general rule, the higher the magnification, the more complicated and specialised does the picture appear, the more difficult is it to appreciate the wood for the trees. Very often a hand lens is all that is required, and it has the advantage of being a far less dangerous weapon than the compound microscope. Dr. Erwin Christeller² has recently reverted to the subject of histo-topography in an article describing a new method of preparing sections of whole organs. The article, which is profusely illustrated, demonstrates very clearly the value of this link between anatomy and histology. While the natural limitations of naked-eye anatomy may fail to demonstrate the structural alterations underlying a pathological process, a too limited adherence to histology may also fail in that it tends to obscure the sense of perspective. But a combination of the two will very often show all that is required. Only those who have paid attention to histo-topography realise how valuable a method of study it can be. Sir Lenthal Cheate has familiarised us in this country with the use of the large section in his study of mammary and other carcinomata, and it is a matter for regret that greater use is not made of the technique.

RECENT RESEARCH ON DISEASES OF THE BLOOD.

WORKERS along associated lines in this country will welcome the summary of recent papers on blood diseases, compiled by members of the staff of the Huntingdon Memorial Hospital of Harvard University under the names of Isaacs, Minot, and Buckman, in the *Boston Medical and Surgical Journal* of Jan. 1st, 1925. The scope of the summary is extensive and indications are given of the nature of the progress made. Under histopathology 40 references to recent publications are given and each element of the blood receives due attention. In Addison's anæmia the great frequency of the following signs and symptoms are recalled in 25 references—namely, the nervous and mental manifestations, the specific gravity fixation of the urine with the increased output during the night, leucopenia, achlorhydria, the presence of macrocytes and megaloblasts in the blood-stream, and the yellow tint of the serum and plasma. The subject of purpura hæmorrhagica (essential thrombocytopenia) receives wide attention, and about 40 cases treated by splenectomy are stated to have been recorded. The results admittedly constitute one of the most striking advances in the therapy of blood diseases of recent years. In this country splenectomy in this disease has been practically untried—indeed, the only cases familiar to us are two which were shown at the Royal Society of Medicine in December last by Dr. G. A. Sutherland. Under leukemia observations on the effects of more adequate irradiation methods in 78 cases of chronic myelogenous

and 50 cases of chronic lymphatic leukæmias show that symptomatic improvement occurs in 95 per cent. of cases. Life is only slightly prolonged however. The basal metabolic rate is shown by several workers to be a better indicator of the severity of the disease than the white cell count per se. The importance of differentiating the fatal condition of acute leukæmia from infective mononucleosis, from which spontaneous recovery is the rule, is stressed. Erythræmia (Vaquez-Osler disease) is next considered from the conclusions of 18 published papers. The familial factor is greater than is supposed. The analogy to leukæmia and the white-cell marrow and erythræmia and the red-cell marrow respectively is made, and the symptomatic group (erythrocytosis) receives attention. Roentgen ray treatment offers some means of controlling the disease, and six workers state that benefit is greater where large doses of short wave-length therapy are given over the long bones. Splenic treatment alone gives little effect. The administration of blood-destroying drugs such as benzol and phenylhydrazin has been tried. Blood disorders in infancy and childhood are extensively summarised from a bibliography of 67 publications. Besides the various diseases, reference is made to little known features, normal and abnormal, of the blood in early life such as coagulation time, bleeding time, volume index, and colour index. The value of this summary of diseases of the blood is heightened by the fact that the bibliography is almost entirely drawn from publications which have appeared during the past four years.

THE CENTENARY OF JOSEPH ROLLET.

THE centenary of the birth of Joseph Rollet, the eminent surgeon of the Antiquaille Hospital at Lyons, was recently celebrated at the Faculty of Medicine of that city, when the various aspects of his life and work formed the subject of addresses by MM. Thibierge, Jeanselme, Nicolas, and Justin Godard, the Minister of Labour and Hygiene. We are indebted to Prof. Nicolas¹ for the following account of his achievements. After graduating at the Paris Faculty of Medicine in 1848 with a thesis on traumatic intracranial hæmorrhages, Rollet came to Lyons, and after unsuccessfully competing for the post of director of the Hôtel Dieu, was appointed in 1850 surgeon-major to the Antiquaille Hospital. Among his predecessors in that office had been two celebrated pioneers in syphilology—namely, Baumès, whose name is often associated with Colles in the well-known law relating to the immunity of the mother suckling her syphilitic offspring, and Diday, the author of the classical work on congenital syphilis. During the nine years that Rollet remained at the Antiquaille, he revolutionised the study of venereal disease as follows. In the first place he proved the erroneousness of the two views for which Ricord had been responsible—viz., the identity of syphilitic and soft chancre and the non-contagious character of secondary syphilis. Secondly, he established the existence of the mixed chancre or the association of syphilis and chancroid, which served to explain the occurrence of constitutional syphilis after what was apparently only a soft sore. Thirdly, Rollet's work was of considerable value in its therapeutic, prophylactic, and medico-legal applications, particularly as regards the dangers of syphilitic infection in the case of glass-blowers and wet-nurses, as well as in arm-to-arm vaccination. Rollet's work was all the more remarkable as it was carried out in the pre-bacteriological era without any laboratory assistance but by his unaided clinical observations. Rollet died on August 2nd, 1894, shortly after he had been appointed professor of hygiene at Lyons and on the very day on which he was to have presided over the Congress of Dermatology. Prof. Nicolas concludes his address by describing him as the greatest syphilographer in the course of three centuries, and one of the prime benefactors of humanity.

OVERCROWDING AND INFECTION.

THE medical officer of health for Sheffield, Dr. F. E. Wynne, regards the overcrowding in that city as more acute than in other urban centres. In the country generally, in spite of the admitted shortage, there was, on the evidence of the Registrar-General, an actual increase between 1911 and 1921 in the number of rooms per person, whereas in Sheffield there was a decrease of 0.04. Much of the worst overcrowding occurs in sublet houses or houses let in lodgings. It is, he thinks, probably unequalled since the 'forties of the last century, and in a paper which he read before the Epidemiological Section of the Royal Society of Medicine on Jan. 22nd Dr. Wynne discusses whether the "frightful influence" of overcrowding, as feared by Lord Shaftesbury and Cobden, still holds in the same measure. Some 40 years ago Dr. J. B. Russell¹ was able to demonstrate a high degree of correlation between the incidence of zymotic disease and overcrowding, the rate per 100,000 of population being 478 in 1-2 roomed houses, 246 in 3-4 roomed houses, and 114 in houses of 5+ rooms. Dr. Wynne has made an analysis of the incidence of scarlet fever and diphtheria in Sheffield according to the number of rooms available, and although the figures are not strictly comparable with Dr. Russell's, yet they seem to Dr. Wynne to justify the suspicion that overcrowding per se has become a less important factor in the spread of infectious disease than it was 40 years ago. In Dr. Russell's figures the increase in incidence of zymotic disease in the worst houses as compared with the best is 419 per cent. In the Sheffield figures, which we reproduce here, the increase is 37 per cent. in the case of scarlet fever and 87 per cent. in the case of diphtheria.

Table showing Incidence of Scarlet Fever and Diphtheria in Sheffield under Different Housing Conditions During the Year 1923.

Invaded households. (I.H.)	Total occupants.		Cases under 15 years of age.	Attack-rate.	
	All ages.	Under 15 years of age.		Per 1000 at all ages.	Per 1000 under 15.
<i>Scarlet Fever.</i>					
I.H. with less than one person per room	1,324	636	342	258	538
Total H. with ditto	145,724			2.35	
I.H. with one or two persons per room	3,694	1784	700	189	392
Total H. with ditto	275,938			2.54	
I.H. with more than two persons per room	1,279	677	186	145	275
Total H. with ditto	57,738			3.22	
<i>Diphtheria.</i>					
I.H. with less than one person per room	367	147	91	248	619
Total H. with ditto	145,724			0.62	
I.H. with one or two persons per room	1,302	615	232	178	377
Total H. with ditto	275,938			0.84	
I.H. with more than two persons per room	492	264	67	136	254
Total H. with ditto	57,738			1.16	

The figures given as the total occupants living under the different degrees of density of occupation in the city represent private families, and are approximate only, exact figures not being available in the Census report for 1921.

The total number of persons in private families was 479,400 (before extension of city), and the total population was 490,639.

Dr. J. Macmillan reported similar increased figures for Woolwich in his annual report for 1923. Should these figures bear criticism, and Dr. Wynne thinks they will, the explanation may be sought either in reduced virulence of the infecting agent or in increased

immunity of the individual attacked. After referring to the remarkable recent decline in the severity of scarlet fever and of small-pox and the practical elimination of enteric fever, Dr. Wynne expresses his belief that there are variations in the infectivity of many pathogenic organisms which make for a lessened incidence of disease quite apart from environmental conditions. He holds that the non-existence of destitution has removed one of the predisposing causes of infection; during all the post-war period of dislocation in trade and of unemployment everybody has been fed, and among the wage-earners and the unemployed fewer people (we are here quoting Dr. Wynne's words exactly) have been overfed. Enforced economy, he thinks, has probably a valuable effect on the selection of dietary in humbler households, and he finds some evidence that the work of Hopkins and Mellanby is percolating through various health agencies to produce a practical effect on the habits of the poorest.

INTERNATIONAL CONGRESS OF RADIOLOGY.

UNDER the joint auspices of the Electro-Therapeutics Section of the Royal Society of Medicine, the Röntgen Society, and the British Institute of Radiology, a Congress of Radiology will be held in London from July 1st to 4th next. The object of this preliminary congress is to bring together radiologists from all parts of the world to discuss subjects of interest, and to secure the formation of a comprehensive international committee and the establishment of a full international congress to be held at stated intervals in different countries. Physics, electro-therapeutics, and allied subjects will be included in the scope of the Congress, to which radiologists from all countries have been invited. Radiological and electro-therapeutic societies are being asked to send approved representatives who shall be eligible to serve on the proposed international committee. In connexion with the Congress there will be exhibitions of apparatus and of radiograms, including dental radiograms. In the week following the Congress visits to other centres of interest will be paid. Arrangements are being made through an agency for travelling facilities and hotel accommodation. The President of the Congress will be Dr. C. Thurstan Holland, the Secretary-General, Dr. Stanley Melville, while Dr. J. E. A. Lynham and Dr. John Muir act as joint secretaries of a large organising committee under the chairmanship of Dr. Robert Knox. All papers intended to be read at the Congress must be sent, not later than May 1st, to the secretary-general, at the British Institute of Radiology, which will be used as the administrative centre for the Congress. Further particulars will be announced in due course. Correspondence and suggestions on any matter in connexion with the Congress are invited, and should be addressed to the Secretaries, International Congress of Radiology, care of the British Institute of Radiology, 32, Welbeck-street, London, W. 1.

It is with regret that we have to record the death of Dr. N. Kulchitsky, lecturer in histology at University College, London, which occurred on Saturday, Jan. 31st, as the result of a distressing accident in the new anatomy building of the College in Gower-street, three days previously. Dr. Kulchitsky, who was for some time professor at the University of Kharkov, Russia, was appointed lecturer in University College three years ago.

CHADWICK PUBLIC LECTURES.—A lecture, illustrated by epidiascope, on International Hygiene will be given by Prof. E. W. Hope in the house of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Feb. 16th, at 5.15 P.M. Sir James Crichton-Browne, F.R.S., will preside. Admission is free.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CVIII.—THE TREATMENT OF ANAL FISSURE.

ANAL fissure, though one of the minor and common rectal conditions, can cause an extraordinary amount of suffering. The prolonged periods of pain, and fear in anticipation of succeeding actions of the bowels, combine to produce a real vicious circle.

It is now generally agreed that fissure results from over-distension of the anal canal during defaecation: a split occurs, usually posteriorly, and if the injury is repeated the tear tends to become deeper and indurated with increasing chronicity. The view originally advanced by Sir Charles Ball that fissure results from tearing down of an anal valve is probably only true in a very small percentage of cases: most anal fissures are at the extreme lower end of the anal canal well away from the line of the anal valves, and, moreover, one sees numbers of cases of enlarged anal papillæ which have not caused fissures.

In women, about 5-10 per cent. of fissures occur anteriorly. There is a troublesome class of case in which multiple superficial fissures tend to occur; this seems to be due to abnormal narrowness of the anal canal, whether as a congenital defect or resulting from contraction of scar-tissue.

Before deciding on the line of treatment to be applied in a given case, it is essential (1) to decide if the fissure is a simple one, (2) to ascertain the local characteristics of the fissure, whether shallow or deep, soft or indurated, and (3) to exclude any other rectal lesion.

Simple fissures form the very large majority of cases seen. The differential diagnosis is not difficult. A tuberculous ulcer has the characteristic discoloured undermined edge of tuberculous lesions elsewhere, and on close examination may be found to be spreading up into the anal canal and down to the peri-anal skin in a manner quite foreign to the chronic simple fissure. Anal fissures occurring in syphilis are generally multiple and associated with condylomata; there will probably be other evidence of the disease and the W.R. will confirm the diagnosis. It may be difficult to differentiate a squamous carcinoma arising in the anal canal in an early stage from a very indurated simple ulcer; in a suspicious case in an elderly subject a section for microscopic examination should be taken through the margin of the ulcer.

Indurated Fissures.—The determination as to whether the fissure is or is not indurated is of vital importance from the point of view of treatment. Induration is a mark of the chronicity of the lesion and a sign that inflammation is taking place around it. The characteristic smooth inflamed tag at its lower margin is due probably to infection and lymphatic stasis, and offers an insuperable barrier to effective drainage of the ulcer apart from operative treatment. A large majority of anal abscesses are found to originate in a chronic fissure which has pocketed; a submucous abscess forms and makes its way externally, pointing just outside the anus. If the fissure is not palpable with a finger, it is clearly a superficial lesion which may heal under palliative treatment.

Associated Rectal Lesions.—It should be the rule in every case of fissure to make a thorough digital examination of the rectum as soon as practicable so as to ascertain whether the fissure is the only rectal lesion. Sometimes it may be impossible to do this except under general anaesthesia, but in most cases, by adopting the methods presently to be described, it will be found possible, either immediately or after a short course of palliative treatment, to pass a finger and perhaps a speculum into the rectum. It is essential to discover if associated conditions such as piles, polypi, proctitis, &c., are present before embarking on any set line of

treatment. The most important condition to exclude is the presence of a carcinoma. The following case is an example of the difficulty in diagnosis in certain cases without general anaesthesia:—

A man, aged 29, came up to St. Mark's Hospital with a typical history of severe pain on defaecation accompanied by slight bleeding. On examination a dorsal fissure could just be made out but was so painful that digital examination of the rectum could not be effected; palliative treatment was given. A week or so later he attended again and was found to have developed an ischio-rectal abscess. He was recommended for admission and was shortly after operated upon under general anaesthesia: when a finger was passed into the rectum the presence of the fissure was confirmed, but above it there was an extensive inoperable fungating growth which was proved in due course to be a carcinoma.

Method of Examination.

Inspection of the anus may show the characteristic oedematous "sentinel" pile, and on separating the anal margin the lower extremity of the fissure may be seen; the stretching may cause it to bleed slightly. Associated conditions such as external piles, evidence of fistula, &c., will be noted.

Palpation of the fissure and digital examination of the rectum should then be attempted; sensitiveness in a very painful fissure can be reduced by local application of a 5 per cent. solution of novocaine, by insufflation with anæsthesin (Ritser) or by injecting its base with 5 per cent. novocaine. The finger, well greased with vaseline and with the pulp facing the fissure, is then passed, and pressure made on the surface remote from the fissure. It should then be possible to differentiate a recent superficial abrasion from a chronic indurated and possibly infected fissure, and also to locate palpable rectal lesions such as foreign bodies, and polypi and other tumours.

Finally, if possible, a small tubular speculum ($\frac{3}{4}$ in. diameter) should be passed and the lower rectum examined. As the speculum is withdrawn the fissure will come into view and very often fibres of the external sphincter muscle will be seen transversely at its base. Sometimes a bead of pus is seen emerging from the fissure: this indicates most certainly that pocketing has occurred and that a submucous abscess has formed, and is a definite indication for operation.

Palliative Treatment.

Only superficial non-indurated fissures can be expected to heal under palliative treatment; the same treatment should, of course, be given to indurated fissures as a temporising measure pending operation, and if for any reason operation is contra-indicated.

(a) *Relief of Constipation.*—Constipation must be relieved and the motions rendered soft and regular. An initial dose of castor oil, 1 oz., is often advisable, followed by paraffin liq., $\frac{1}{2}$ oz. t.d.s., with senna or cascara at night, p.r.n. It is a good plan to instruct the patient each night to run into the rectum through a small rubber catheter and funnel about 3 oz. of warm olive oil; this may be retained all night with the help of a pad of wool and a T-bandage, and will render the morning stool smooth and painless.

(b) *Relief of Pain and Sphincteric Spasm.*—General treatment in the way of pot-bromide, gr. xx. t.d.s., with aspirin gr. x. nocte will be useful. Local treatment consists in the application of sedative ointments and suppositories. The following ointments are suitable for introduction after each action of the bowels either digitally or by means of an ointment introducer attached to a collapsible tube: Bismuth subnitrate, $\mathfrak{z}$ ii.; cocaine, gr. x.; lanoline, $\mathfrak{z}$ i., or hydrarg. subchlor., $\mathfrak{z}$ ss; pulv. opii co., gr. x.; extract belladonna, gr. v.; lanoline, $\mathfrak{z}$ i. At night a suppository containing extract of belladonna gr. 1 may be inserted, with addition to it of morphine acetate gr. $\frac{1}{4}$ if pain is severe.

(c) *Local Applications* at intervals of a week or two may be given to the fissure through a speculum to stimulate healing and form a protective covering to the raw surface. Pure ichthyol may be applied on a glass rod, or the fissure touched with silver nitrate or nitric acid (Hilton in "Lectures on Rest and Pain").

Operative Treatment.

Thorough preparation is most important seeing that the majority of these cases are very constipated, often with hard scybalæ impacted in the rectum. Castor oil, 1 oz., is given two nights before operation, followed by a dose of salts in the morning. On the evening before the operation a soap-and-water enema is given, and an astringent mixture by the mouth containing tincture of opium (℥ x.) and tincture of catechu (℥ss). A half-pint rectal wash-out of plain water is administered on the morning of operation and is repeated if necessary. The usual hypodermic injection of morphia and atropine is given before operation.

The operation of incision of a fissure is designed simply to give drainage. After careful antiseptic preparation with ether soap and lysol solution (3i. to Oi.) an incision is carried from the upper end of the fissure out on to the peri-anal skin to the extent of about 1-1½ inches. The safe rule in this connexion is to make the external part of the incision double the length of the internal. A few of the fibres of the external sphincter may be divided, if it seems necessary, to secure adequate drainage. Complete division of the sphincter is never required. The lateral skin margins are then excised, including the sentinel tag, leaving a flat oval-shaped wound. Any accompanying rectal polypi, hypertrophied papillæ, or piles are removed at the same time. Some sterilised vaseline is injected into the rectum: a piece of drainage tubing and dressing with dry cotton-wool complete the operation. The wound is left to granulate. It is

unwise to attempt a primary suture of the wound as the results of this operation are most uncertain.

After-treatment.—Careful attention is given to local cleanliness. The bowels are opened on the third day and after this the patient should have a warm bath twice daily. The wound is dressed with flat cotton-wool swabs moistened with dilute perchloride or carbolic lotion; they should be inserted so as to keep the skin margins separated until healing takes place, which should be in about three weeks. If healing is slow, brilliant green or scarlet red ointment may be applied. As an alternative to general anæsthesia, operation may be performed under spinal, sacral, or local anæsthesia. If the last method is decided upon the external sphincter should be put out of action by injecting into it on each side of the mid-line posteriorly about 5 c.cm. of 2 per cent. novocaine. The perineal branch of the fourth sacral nerve and part of the inferior hæmorrhoidal nerve will be blocked and a good degree of relaxation obtained. The operation can then be continued in the usual way after infiltration of the operation area.

The old operation of "stretching" the sphincter is now rarely performed. It is unsuitable for a chronic fissure and in a recent fissure a deep laceration is liable to occur—moreover, the sphincter is liable to be torn rather than stretched. The object of operation in a chronic fissure can be summarised in the one word—drainage.

Assistant Surgeon, St. Mark's Hospital; Surgical Registrar, Middlesex Hospital.

Medicine and the Law.

REX v. BATEMAN IN THE COURT OF CRIMINAL APPEAL.

IN the Court of Criminal Appeal on Feb. 2nd Dr. Percy Bateman was granted leave to appeal against his conviction for manslaughter at the Central Criminal Court on Dec. 9th, 1924, when he was sentenced to six months' imprisonment in the second division. The application was made on behalf of Dr. Bateman by Mr. Norman Birkett, K.C., with whom was Sir E. Marshall Hall, K.C., and Mr. Arthur Davies. The court was composed of the Lord Chief Justice (Lord Hewart), Mr. Justice Salter, and Mr. Justice Fraser.

The prosecution, as will be remembered, arose out of the death of Mary Anne Harding, a woman patient of Dr. Bateman, whom he attended in childbirth, having been called in by a midwife in consequence of complications having arisen, and who afterwards died. Facts not disputed by the defence were that the death followed and was due to the removal of the uterus of the deceased in the course of delivery by the accused, following a complex presentation, and that the accused took no steps to have his patient taken to a hospital until some days later; also that at the hospital she survived her removal by 30 hours. It was, however, denied by the defence that the avulsion of the uterus was caused by criminal negligence on the part of Dr. Bateman, and it was equally part of his case that the delay in removing the woman to the hospital had not accelerated her death or diminished her chance of recovery, and was not due to any desire to cover up his conduct. It was urged on his behalf that immediate removal in the condition in which she was would have been accompanied by grave risk of causing her death.

The matters formally stated by the appellant as the grounds upon which he desired to appeal were that the verdict was not in accordance with the evidence of the medical experts, that Mr. Justice Shearman had misdirected the jury on the law and on the facts, that evidence had been wrongly admitted, that the judge had dealt with matters which were for the jury to

decide, and that the verdict was against the weight of evidence.

Mr. Birkett began his argument with a brief statement of the facts bearing upon his application, calling particular attention, with regard to the question of removing the patient to a hospital directly her condition was realised, to the fact that she lay in a room on the fourth floor approached by a narrow staircase. He was arguing that there had not been shown at the trial that there was any negligence in the delivery of the child, when the Lord Chief Justice interposed, saying that there was evidence of pulling, and pointing out that, after it had been made plain that the uterus had come away with the placenta, the accused took no steps and had concealed the matter. With regard to this it was pointed out by counsel that the words admitted by the accused as having been said to the midwife were to the effect: "We had better keep this to ourselves and not tell the relatives," and that his only wish had been not to distress the relatives by informing them of what had happened. Mr. Birkett proceeded to argue that in summing up to the jury Mr. Justice Shearman had said that, in order to convict of manslaughter, there must be proof of gross and culpable negligence, without instructing the jury as to what, for the purpose of a criminal charge, was implied by the qualifications "gross" and "culpable." He referred to *R. v. Doherty* (16 Cox, 306), *R. v. Williamson* (3 C. & P. 635).

In *R. v. Doherty* (in which the charge arose out of a man having shot another with a revolver) Mr. Justice Stephen said (at page 309): "Manslaughter by negligence occurs when a person is doing anything dangerous in itself and conducts himself in regard to it in such a careless manner that the jury feel that he is guilty of culpable negligence and ought to be punished." As an illustration Sir Fitzjames Stephen suggested that if a man performing a surgical operation, either because he lost his head or from forgetfulness, did something he ought not to do, or omitted something that he ought to do, there would be negligence, but that, if there was only the kind of forgetfulness common to everybody, it might furnish a ground for claiming civil damages, but not for making a criminal charge. It would be otherwise if, for example, the surgeon went to attend the case when drunk, and through his drunkenness caused the loss of his patient's life. In *R. v. Williamson* a

man-midwife was on trial for manslaughter having torn away part of the prolapsed uterus of a patient supposing it to be part of the placenta, through which the patient had died. Lord Ellenborough told the jury that in order to substantiate the charge of manslaughter, the prisoner must have been guilty of criminal misconduct arising either from the "grossest ignorance or the most criminal inattention." Lord Ellenborough added: "It would seem that, having placed himself in a dangerous situation, he became shocked and confounded. I think that he could not possibly have committed such mistakes in the exercise of his unclouded faculties, and I own that it appears to me that if you find the prisoner guilty of manslaughter, it will tend to encompass a most important and anxious profession with such dangers as would deter reflecting men from entering into it."

Mr. Birkett submitted that there had been no evidence of negligence at the delivery of the deceased, and that the case should not have been left to the jury.

Their Lordships having consulted, the Lord Chief Justice intimated that counsel, whom he complimented on his able argument, had shown that there was a substantial question to be argued, and that the court would give leave to appeal. Mr. Birkett then referred to the great importance of the case to the medical profession, and to letters that had appeared in THE LANCET since the trial, which suggested that fresh evidence might be available as to the medical questions raised.

Lord Hewart said that if, in addition to the evidence taken at the trial, the appellant's counsel brought fresh evidence to the Court of Criminal Appeal, the question whether it should be admitted might then be decided according to the course taken by the appeal.

It is presumed that argument on the appeal will be heard on Feb. 9th or on some subsequent Monday.

Special Articles.

ON THE ABSENCE OF PROGNOSTIC CRITERIA IN CHRONIC INFLAMMATION.

BY MARTIN O. RAVEN, M.D. OXF., M.R.C.P. LOND.,
MEDICAL OFFICER, ST. MARY'S HOME, BROADSTAIRS.

THERE is a need of criteria in determining the course and prognosis of chronic inflammatory disease. It will generally be found, from the perusal of text-books and other general works on medicine, that in the case of those diseases which spread themselves out over periods of months and years, the question most nearly affecting the patient, namely, "When will he be well again?" or, more technically speaking, the questions of the course and prognosis of these diseases—these questions are left to the imagination of the reader for answer, aided by the preceding pages devoted to symptomatology and diagnosis. Here and there certain symptoms and signs are mentioned as arising during the course of chronic inflammatory disease—e.g., albuminuric retinitis and pulsus alternans, which are pointed out as unfavourable omens, but the general result of an outlook which omits a detailed analysis of the time element in disease is necessarily a hand-to-mouth treatment and a day-to-day prognosis.

Absence of Outlook.

Now the reason for this existing outlook or absence of outlook is not very difficult to discover: patients suffering from chronic disease often change their abode and change their medical attendant and thus make continuous observation difficult, and a clear image of the course of a chronic inflammation can only be built up by continued observations made upon slowly-altering physical signs: such images

are too likely to be overshadowed by those of more acute diseases unless studiously preserved, and the result is that there are very few of them presented to the readers of medical text-books to-day. That there are exceptions to this rule, especially in tuberculosis, will be emphasised later.

Now, chronic inflammatory diseases may conveniently be divided into two groups of unequal size: (1) A smaller group, in which we have direct medical or surgical means of attacking a known cause of the inflammation: examples are syphilis, chronic appendicitis, and many cases of tuberculous adenitis of the neck. (2) A far larger class, in which the inflammatory agent may be either unknown or known, but in which only indirect treatment is possible. In these cases we can only place the patient in such a favourable environment as, we hope, will enable the natural forces of the body to overcome the inflammation. The following examples may be given: Most forms of tuberculosis; chronic bronchitis; hyperplastic colitis; fibrosis of the lung; carditis following upon rheumatic infection; chronic nephritis, parenchymatous and interstitial; and chronic mono- and poly-arthritis. In most of the above diseases it is impossible for the physician, in the present state of knowledge, to define a course or give an approximately accurate prognosis in a given case: indeed, the only cases where accurate definition of course and prognosis is forthcoming are usually so advanced as to make a favourable outlook impossible.

Tuberculosis an Exception.

In tuberculosis, however, we have a noteworthy exception to this general position. So much systematised work has been done both in phthisis and in surgical tuberculosis of childhood, that it may be said that, given the coöperation of the patient and the patient's family, and given sufficient time, a favourable result may be confidently anticipated in the majority of early cases: further, a length of time, generally of several years' duration, may be laid down, during which strictly systematised and graduated treatment must be adhered to, and moreover certain criteria may be defined, like milestones along the course of recovery, indicating the amount of retrogression of the inflammation and enabling appropriate modifications of treatment to be made. As examples of such criteria, we may take the cessation of sustained pyrexia after exercise in phthisis, and in tuberculous hip-joint disease the disappearance of the reflex contraction of the psoas muscle produced by eversion of the lower limb. These and other criteria mark the attainment of certain stages towards recovery, and have enabled a minimum time-limit for the whole illness to be laid down for the benefit of all cases of these diseases. Where, in tuberculosis, no such systematic management is adopted, the prognosis must be considered grave, and if a certain number of cases appear to effect a more or less spontaneous recovery, such recovery is the result only of the fortuitous interaction of unknown factors and reflects no credit upon the management of the patients.

This haphazard condition of affairs, which necessarily still exists in many thousands of cases of tuberculosis, prevails in a still higher proportion of other chronic inflammatory diseases, in which little or no systematic investigation into their course has been made. An enormous proportion of patients suffering from them drift about dependent for treatment upon symptoms and signs of very doubtful significance, and it may be doubted whether under such conditions the benefit to one individual of a spontaneous recovery is not outweighed by the danger to others from the undue optimism which it may engender in the mind of the medical attendant. The rheumatic diseases of childhood, which, as is still hardly comprehended, stand easily second to tuberculosis in destroying and shortening life in childhood and later life, are the most depressing example of a national disease which takes an enormous toll of life, because the patients necessarily set out upon a road of unforeseen pitfalls, leading too often to a disastrous end. The small

amount of systematic work which has hitherto been done in this disease points tentatively to the need to remove the patients from the environment in which they first became infected into fresh air for periods of at least six or eight months, and to secure for them a large measure of physical rest, if grave consequences to the heart are to be avoided. Further, during this course of treatment, certain criteria may be defined, marking the arrest of active infection of the myocardium and endocardium: the chief of these are disappearance of anæmia, the slow return of the pulse to normal, often associated with a return of its normal respiratory variation, and stabilisation of the physical signs given by the heart.

Definition of a Minimum Normal Course.

The subject may be opened further: is it not likely that systematic investigation would discover that in the case of other chronic inflammatory diseases there is a minimum normal course which may be anticipated provided that time and the most favourable environment possible be allowed to operate on behalf of the patient? Might not in them, also, certain criteria be elicited, defining the attainment of certain stages on the road to recovery? In tuberculosis and rheumatic disease, not until the constitutional signs have disappeared and the physical signs of the disease have ceased to vary, can it be said that a quiescent stage has been reached and that fairly complete rest may be allowed to be slowly modified; and it would seem that these simple principles may well be applied to other forms of chronic inflammation. Constitutional signs will, by common consent, always necessitate rest and care in every case, but physical signs are harder to observe accurately over long periods of time; the following are tentatively suggested as examples and as possibly able to furnish evidence of the cessation of active inflammation:—

1. *Nephritis*: Constancy in the amount of albuminuria on a constant diet; and constant blood-urea over a length of time.
2. *Colitis*: Cessation of mæna and diarrhoea.
3. *Arthritis*: Restoration of cleaner outlines of joint cartilage in radiograms.
4. *Fibrosis of Lung*: Quantity of morning sputum constant; X ray findings and clinical signs constant in three examinations spread over six months or more.
5. *Rheumatic carditis* (already referred to): Loss of excitability and rapidity of heart beat; stabilisation of physical signs of the heart; return of the respiratory variation of the pulse.

In these diseases, exactly what constitutes the most favourable environment for the patients is a question that only systematised investigation over lengths of time would show: hygienic conditions, however, especially as regards sunlight and fresh air, are of obvious importance; adequate warmth is essential in most cases, and, apart from colitis, a liberal diet is indicated. The requisite amount of rest is a far more debatable point, but in both tuberculosis and rheumatism it will be found that excessive activity is a great cause of relapse and recrudescence. Hence it seems that, while due consideration must be given to the view that the body to be healthy must be active, yet that activity should be so carefully graded as to represent in effect a gradual modification of the amount of rest considered necessary at the beginning of treatment. According to these principles, cases of carditis and nephritis should be allowed to get up little by little after a prolonged period of bodily rest; in colitis adequate rest is secured to the bowel by a reduction to a minimum of cellulose and other indigestible material; while in chronic arthritis a normal position of the joint may only be obtainable by some weeks of weight extension, following on which a slow return to normal activity may be allowed.

The course of chronic disease is a subject over which there is at present much obscurity. Prof. Hugh MacLean states in his monograph on Glycosuria and Diabetes (p. 157): "There are few, if any, chronic pathological lesions which tend to cure, no matter what the treatment, when they have been established

for a year or two." But, if once it can be shown that in a given disease there is a tendency towards a certain course being run (as in tuberculosis and, perhaps, rheumatic disease of childhood), so long as environment is favourable and established early: then the questions of prognosis, which are those which most nearly affect the patients, stand in some chance of being answered.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

FURTHER SITTINGS.

(Continued from p. 188.)

THE Commission resumed its sittings on Jan. 26th. the Chairman of the Commission, Mr. H. P. Macmillan, K.C., presiding.

THE CASE OF MR. HOLMAN.

The case of Mr. Holman was further considered. Mr. Stewart again appeared for Mr. Holman, Mr. Dickens, K.C. (instructed by the Medical Defence Union as to five of its members), and Mr. Croom Johnson watched the proceedings on behalf of certain doctors concerned and Moorcroft Mental Hospital.

The Chairman said Mr. Holman had addressed a most improper letter to the Commission, casting reflections on a doctor who was to be examined, and he understood numbers of other letters had been received. That letters should be so addressed, or to any parties in the case, was most improper. The Commission wished to learn the reasons in this case for issuing an urgency order, instead of the usual, slower, reception order; also the manner and circumstances of the certification. This was mainly to see whether there were at present adequate safeguards against wrongful certification. Also the treatment in Moorcroft would be inquired into.

Examination of Sir Maurice Craig.

Sir Maurice Craig was called and sworn and examined by Mr. Dickens, K.C. He said he first saw Mr. Holman in January, 1915, in consultation with his own doctor, when a history of the condition was given him, from which it seemed that several members of the family were of unsound mind. He was stated to have been very excitable and talkative for two years, and to have been a good deal worried by the war. At one place he had tried to throw himself out of a hotel window, and later he cut himself, and eight persons were required to hold him down. At certain periods he thought he was liable to arrest and execution as a German spy, but at other times he seemed normal. While in the nursing home he never appeared to have attempted self-injury. He at this time lost a stone in weight and said he felt physically wrong. When Sir Maurice Craig saw the patient at Dr. Dempster's home the pupils were normal, but soon afterwards changes took place in the physical signs. In reply to a question, Sir Maurice Craig said he always took the human side and did his best to avoid sending people to a mental hospital. The patient's wife showed fear of having him back at home again. He was said to have got into bed on one occasion with his wife while he was wearing his boots, hat, and overcoat, was afraid of being in enclosed spaces, and, though married, showed much interest in a matrimonial agency. He wandered from one subject to another in conversation, his pupils were not reacting well to light, and his knee-jerks were sluggish and unequal. At that time Sir Maurice Craig had no reason to suspect syphilis. Dr. Adler found Wassermann reaction of the blood doubly positive, and that of the cerebro-spinal fluid also positive. There was a high lymphocytosis, about 86 per cent., indicating something pathological.

The witness was closely questioned concerning the significance and reliability of the Wassermann test and the usual behaviour in general paralysis of the insane. He said the result of the Wassermann would

not have influenced his view as to Mr. Holman's mental condition, but it afforded a valuable clue to the condition he was suffering from. He also stressed the periods of remission, during which the patient might behave in a more or less normal way; also the fact that some cases of G.P.I. did not progress beyond a certain stage.

As to why an urgency order was used, Sir Maurice Craig said the patient was at Dr. Dempster's house, and there was no power of restraint. Mr. Holman threatened to leave by himself, and the likelihood was that if that happened he would soon get into the hands of the police, as he was not in a fit state to take care of himself. Sir Maurice Craig tried once more to avoid sending the patient to a mental hospital by drawing up and getting signed by Mr. Holman an undertaking to carry out certain promises, but this was broken, simply, the witness considered, because he was unable to keep it. A certificate had already been obtained for his detention, but it was not used. Wishing to call in somebody to whom the case was quite new—Dr. Stoddart having signed the unused certificate—he asked Dr. Percy Smith to see the patient, and Dr. Smith had a long interview with him alone. What Sir Maurice Craig saw and knew of the patient certainly justified his detention in a mental institution.

Mr. Stewart commenced his cross-examination by asking as to certifying doctors' fees. Asked why he did not tell the patient he was suspected to be suffering from syphilis, Sir Maurice Craig said that in the circumstances he would not do it; a man disturbed in mind might easily have been made worse by such a remark. If syphilis were present in a patient in the primary infective stage it would be the duty of the medical man to inform the patient and ensure that others were not contaminated. Mr. Stewart questioned the witness to show that Mr. Holman having recovered, he could not have had G.P.I.; and Sir Maurice Craig said he had known a captain with the disease take his ship to Australia and back during a remission. At a subsequent stage the Chairman expressed regret that the opportunities Mr. Stewart was enjoying in cross-examining the witness were being largely wasted by this covering up with irrelevant matter, apart from the time of the witnesses and others being valuable. Sir Maurice Craig agreed that no one of the symptoms and things observed and stated on the certificate would, of itself, constitute a sufficient reason for detention as of unsound mind.

Mr. Charles R. Steel, a solicitor, spoke to visiting Mr. Holman at Moorcroft in the interest of relatives and executing a codicil revoking Mr. Holman's will in 1917. He did not think Mr. Holman was of unsound mind when he saw him at Moorcroft. Mr. Holman urged him to procure his release, but he took no steps to that end as he did not want to set his opinion against that of the doctors.

Examination of Dr. Stoddart.

Dr. W. H. B. Stoddart said he first came into contact with Mr. Holman in 1916, and produced the notes he made of his condition at the time, taken at the home of Dr. Dempster at Croydon. The question was as to whether he was in a condition to go unaccompanied to Brighton, as he intended doing, and the witness considered he should not go anywhere without proper supervision and control. He concluded that the patient had G.P.I., but it was an atypical case. The urgency order was rendered necessary by the patient's determination to leave and the fact that there then existed no power to detain him.

The witness was cross-examined as to his recently modified views in favour of Freudism, and admitted that he now looked at the pathology of mental disorders from a somewhat different angle. But this did not change his opinions on the question whether a given patient was certifiable. He added that there were impressions derived from a long interview with a patient which could not be adequately represented on the form of certificate. Answering the allegation, put

to him by Mr. Dickens in re-examination, that he certified because he was told to do so, Dr. Stoddart said no doctor would do that; all he was asked was his opinion, and he formed a very firm opinion.

Dr. R. J. Stillwell, of Moorcroft Mental Hospital, said this patient was associated there with patients of his own class and social standing, and he was one of the most talkative and one of the least normal of the whole of them.

On Jan. 27th Mr. Holman's case was further inquired into.

Dr. Percy Smith said he saw Mr. Holman in December, 1916, and the information supplied to him by three doctors added to what he himself found on examining the patient led to his decision that Mr. Holman was insane and that he should not longer remain at Dr. Dempster's house. Answering Mr. Stewart in cross-examination, Dr. Percy Smith said that within the limits of safety he would do his best, as he always did, to avoid actual certification. He did not give any warning to the patient that what he said might be material to justify his detention, it would have been detrimental. He had no regret for having certified Mr. Holman as insane.

Dr. Porter Phillips, medical superintendent of Bethlem Hospital, said Sir Maurice Craig asked him to see Mr. Holman. He did so, and found him restless, excited, and very talkative; the latter trait seriously interfered with questioning. The pupils were unequal, the reflexes exaggerated, and there was marked tremulousness. He was, in witness's opinion, of unsound mind. The patient said he was willing to go to a home, mentioned by the witness, for treatment, and it was decided to take advantage of this willingness to transfer him to Moorcroft, and this was done. It certainly was not a trap.

The Chairman intimated that there would be no need to call Dr. R. H. Cole, who was in attendance, as sufficient evidence had been already taken.

Evidence of the National Society for Lunacy Reform.

Mr. Montgomery Parker, chairman of the National Society for Lunacy Reform, was then called and examined. He urged that voluntary hospitals should be at once provided with a State subsidy and should be under the control of the Ministry of Health, through local authorities, and free of association with the Board of Control or other department of the Government. Also, general hospital wards should be adapted for dealing with incipient mental cases, and those with temporary derangement associated with an acute physical condition. The Society also wished for an arrangement in infirmary wards which would permit of a more efficient classification of cases and their observation. He further asked that, on the legal side, methods of certification and the issue of reception orders should be unified, and pressed for removal of distinctions between private and rate-aided patients. There should be adequate representation of the patient at all stages. Improved methods of curative treatment and better environment of patients, where necessary increasing the nursing and other staffs to ensure this; a statutory requirement on all institutions to appoint a body of authorised visitors, independent of lunacy administration, and licensed; and the introduction of the judicial authority within asylums were further points submitted. The Society also favoured the independent access of medical men to patients. The senior medical officer of an institution should not, the Society considered, be charged with administrative duties. After discharge there should be an extension of opportunities and facilities for after-care.

On Jan. 28th Mr. Parker's examination was continued.

The Chairman said that when a patient recovered from a mental illness it was difficult to determine the exact date of convalescence, and in many cases it would not be wise at once to restore the patient to his former conditions of life. One solution was to make the patient a voluntary boarder when this stage of progress had been reached; another was to use the

parole system, though this would mean some contravention of the law, as a patient on parole had not the same freedom as a sane person.

Mr. Parker said he would make such a patient a voluntary boarder; he realised the necessity of inquiring as to a patient's home conditions before returning him to them. For rate-aided patients the only course seemed to be to send them back to the infirmary. His Society was anxious that a more judicial character should be given to all the proceedings prior to detention, and there should be the right of cross-examination at the inquiry, and the power to call rebutting evidence.

The Chairman pointed out that a similar requirement was urged by the British Medical Association.

Mr. Parker said his Society did not favour doctors passing on their responsibility; what was required from the medical man was a medical report, for which he would be held responsible.

In answer to the Chairman, Mr. Parker agreed there might be cases in which it would be inexpedient to disclose the medical opinion to the patient; if the judicial authority functioned efficiently, the proposals of the National Society for Lunacy Reform would be modified to that extent. He did not think disclosures in regard to lunacy were any more serious than those in divorce, and residence in a mental hospital would become known generally, sooner or later. One strong recommendation was that the patient and his friends should know what steps were open to him to defend himself. Also statements made on hearsay should be brought to the notice of the patient, as they might be susceptible of a reasonable explanation.

Lord Russell pointed out that if the patient were of unsound mind his denial or explanation could not be accepted, and the witness said he meant that a statement of a patient, for instance, should not be regarded as a delusion until it had been investigated, and hearsay should not be accepted without the same process of checking.

The witness quoted a case in which an alleged lunatic insisted on her own moral unworthiness, and it appeared clear that she had a strong religious bent and displayed that moral subjugation which was a condition precedent to Divine pardon. He thought it very necessary that, except on an emergency order, the judicial authority should see every patient.

The Chairman said that point need not be laboured, as there had been a complete consensus of testimony on it. If the judicial inspection was efficient, not perfunctory, he did not see that two medical certificates were necessary; he would be satisfied with the power to call in a second doctor if required. This, he hoped, would be a deterrent to an inexperienced man in lunacy acting in this regard. The certifying doctor should see the patient a second time—i.e., with the justice after he had certified him—and could be required to explain any ambiguous statements on his certificate. The doctor should be able to give evidence on hearsay, as witnesses could not be brought for the purpose from any part of the country. At the second visit the doctor could usefully advise as to the institution the patient could be sent to. The magistrate could compel the attendance of relatives. He agreed that some statements about a patient's condition and prospects could not be made in the patient's presence; and the justice could not exercise discretion in the matter, as he would not know what statements were likely to be made.

Sir David Drummond questioned the witness as to whether he had any cases to bring in which it was alleged patients were wrongly certified, and Mr. Parker said there were cases in which the mental disturbance was of only short duration and the cases should not have been dealt with by certification. Sir David Drummond asked that certificates in one case might be brought in which this was alleged, and the witness promised to comply.

Another contention of the witness was that when a patient was capable of making rational statements an inquiry into his case should be conducted publicly, and Earl Russell asked whether it was really desired that

in addition to the relatives and other parties interested, the local reporter should be present, and serve up for the public all the medical and other details. The witness agreed there were difficulties surrounding this requirement, but such a condition as delirium in an acute physical illness, as in pneumonia, was an improper ground for certification. Earl Russell and the Chairman agreed. Finally, the witness said nothing was to be gained by publicity if the judicial authority could be relied on to function properly.

Mr. Parker said few of the public, and not many practitioners, seemed to know what rights a patient possessed under the Lunacy Act, and they were not in a position to secure a copy of the Act when required. There should be a copy of the Act in the possession of every medical officer of health, and it would be a valuable step to have printed for popular use on a card or in pamphlet form the main provisions of the Act in simple language.

The Chairman and Earl Russell agreed this would be a very important document to issue.

The remainder of the sitting was occupied with a discussion of Mr. Parker's proposals for greater liberty in the matter of correspondence for the patients. It was pointed out that in a number of asylums there were locked letter-boxes, and some—the great majority—of the letters written by patients were not fit for anybody to read, hence the censorship which was exercised. The witness considered that if letters were written making complaints, the writers were penalised.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

THE PROVISION OF MEDICAL BENEFIT.

THE official account of the Scope and Administration of Medical Benefit (Section C of the Appendix) was supplemented by the oral evidence of Mr. L. G. Brock, C.B., Assistant Secretary in charge of the division of the Ministry of Health administering the medical benefit provisions of the Acts, and by Dr. J. Smith Whitaker, the Senior Medical Officer of the Ministry concerned with this work.

Central and Local Administration.

The local administration of medical benefit is in the hands of committees, called Insurance Committees, set up for each county and county borough.

(Q. 897.) The statement gives the impression that these Insurance Committees have not much independent voice in making the arrangements for the provision of medical benefit in their respective areas. Is that the case?—A. That is so. . . . The medical profession at a very early stage insisted on central negotiation in regard to the settlement of the capitation rate, and even if it had not been [so], it would, I think, in practice have been quite impossible for Insurance Committees to carry on negotiations in their own areas and to make the sort of arrangements that were contemplated by the original Act with all Approved Societies.

Representatives of Insurance Practitioners.

(Q. 899, 900.) The body representing the medical profession with which the Ministry negotiate is the Insurance Acts Committee formed by the British Medical Association. Constitutionally it has the position requisite for doing so. In every insurance area there is a statutory body (the Panel Committee) elected to represent the insurance practitioners of that area. These Panel Committees, in conjunction with the Local Medical Committees set up under the Act of 1911, elect delegates to conferences held from time to time, and those conferences have since about 1915 recognised the Insurance Acts Committee

* In a previous article the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247-8.) References to the official statement which has been issued as an appendix in four sections are given thus: Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

appointed by the British Medical Association as their executive body. The Insurance Acts Committee reports formally to the conference, the report is laid before all Panel Committees, and their delegates are instructed with reference to that report, so that the authority of the Insurance Acts Committee to represent insurance practitioners is constitutionally derived from the insurance practitioners by a direct chain.

(Q. 929.) Asked whether the consultation with the British Medical Association (or, in the case of chemists, with the Retail Pharmacists' Union) has had the effect of diminishing the importance of the local Insurance Committees, Mr. Brock said:—

I do not think it can be said to have diminished their importance because it is work which they never did. It has made them, I think, considerably less important than the framers of the Act contemplated that they would be.

Cost of Local Administration.

The total cost of insurance committees' administration in England and Wales is £360,000 per annum, or rather less than 5 per cent. of the cost of medical benefit. (Q. 914.) It includes the cost of day-to-day administration and the investigation of complaints; in the main it represents expenditure on the maintenance of various indexes which are necessary, firstly, to prove the title of the insured person to medical benefit; secondly, to attach him to a doctor; and, thirdly, to calculate what is the amount of work, or rather the number of patients accepted by a doctor, and therefore, what share of the total pool available to the area should be allocated to him.

Ready Access to the Insurance Committee.

On the question whether it would be more economical and equally efficient if, for instance, the work were done by county committees only, Dr. Smith Whitaker said:—

(Q. 928.) It is a great advantage in a fair-sized borough that you should have an official of the local committee to whom the insured persons and doctors and everybody can have free access. If you were to centralise the work too much—the actual administration of medical benefit, apart from book-keeping, and that kind of thing—you would not have that ready access which does a good deal to make the thing work smoothly. We should have more complaints if it were not possible for the insured person to go and talk things over with the clerk, and the clerk to talk things over with the doctor.

The "Representation" of Insured Persons.

Every Insurance Committee has a substantial medical element, but there is always a majority of representatives of insured persons.

(Q. 959.) When you speak of these people representing insured persons, they are really selected not by the members of the society, but by the Committee of Management, are they not?—A. I do not think the member of the society has any voice whatever in the election in most cases.

Panel and Local Medical Committees.

(App. C. 10.) The Act of 1913 made provision for the constitution of a statutory body in each area known as the Panel Committee, which is elected by the insurance practitioners in the area under approved schemes. It is representative of the collective opinion of the insurance practitioners in the area, and the Insurance Committee is required to ascertain through the Panel Committee the opinion and wishes of insurance practitioners on matters affecting the local administration of medical benefit. It is optional whether there shall also be a Local Medical Committee, and their functions are limited.

(Q. 961.) Could you tell us briefly what is the exact difference between the Local Medical Committee and the Panel Committee?—A. For practical purposes in the great majority of areas there is no difference at all.

Why the Benefit was Limited to General Practitioner Treatment.

(Q. 995.) In practice medical benefit has been limited to treatment of the kind which an ordinary general practitioner can properly render, and in the Regulations which have been issued under the Insurance

Acts and which govern the administration of medical benefit that interpretation has been followed.

(Q. 995.) Can you tell the Commission on what provisions of the Insurance Acts that view of the scope of medical benefit is based?—A. That view was based on the advice given to the Insurance Commissioners by their legal advisers. . . . If every doctor had a right to come on the medical list and every insured person had one, and not more than one, doctor, it seemed impossible to avoid the inference that the scope of medical benefit must be construed as being limited to services which were within the competence of the average general practitioner. Of course, that construction of the Act is admittedly inferential, but had the view taken by the Commissioners been open to question it could very easily have been challenged in the Courts. No attempt ever has been made to challenge it in the Courts. . . . [Further] it was felt that if all doctors were to receive the same rate of remuneration, that implied a uniform obligation, a uniform content of service, and that it would not be equitable to require one man, because of the accident that he possessed some special skill, to render a wider range of service than the rest of his brethren on the medical list.

(Q. 1001.) During the passage of the Bill of 1911 the discussions were influenced by the scope of the treatment provided by the old friendly societies. Usually that was treatment more limited than the general practitioner service provided by the Act—e.g., it was a local service and did not provide for the member when he left the area in which his club or society operated. (Q. 1004.) As to the possibility of including some kinds of specialist treatment and excluding others, the witnesses said that no warrant could be found in the Act for this course. It being a question of all or none, and having regard to the fact that the fund was limited and that insured persons could claim whatever the benefit was as a matter of right, the authorities concerned were justified on practical grounds in the course that they took.

Services Outside the Scope of the Contract.

These may be such services as dental treatment not ordinarily given by a doctor. (Q. 1006-9.) As to this, it was stated that a doctor finding a condition of ill-health due to defective teeth could only advise the patient to go to a dentist; if his suggestion were not carried out he must continue to do the best he can for the patient. (Q. 1010.) As to specialist services which an ordinary practitioner would not, as a rule, render, the position is as follows:—

If the patient desires that the doctor should render it, the latter must first of all explain that, in his view, it is outside the scope of the service he is bound to provide under his contract, but if the patient [still] desires that he should perform the service—for example, examination of defective eyesight, prescription for spectacles or something of that kind—he may undertake it and charge a fee. But in any such case he must, within two days after giving the treatment, furnish the Insurance Committee, on a form supplied by them, with particulars as to the service.

The onus is then thrown upon the doctor to show, if called upon, that it is a service not covered by the contract. The Local Medical Committee would first bring their medical opinion to bear on the question and at a later stage the matter may be referred by the Minister to referees. (Q. 1012.) Services are deemed not to involve the application of special skill and experience unless the doctor concerned proves either—

(App. C. 39.) (a) That he has held hospital or other appointments affording special opportunities for acquiring special skill and experience of the kind required for the performance of the service rendered, and has had actual recent practice in performing the service rendered or services of a similar character; or

(b) that he has had special academic or post-graduate study of a subject which comprises the service rendered, and has had actual recent practice as aforesaid; or

(c) that he is generally recognised by other practitioners in the area as having special proficiency and experience in a subject which comprises the service rendered.

(Q. 1080-1096.) The fact that a particular service which an individual practitioner having special skill might be competent to render could be withheld unless the patient was prepared to pay for it, has given rise to criticism of the service. It was recognised in the early days of the Acts that the services which

insured persons could receive for uniform contributions would be a uniform benefit and that different obligations could not be imposed on different doctors having different degrees of skill. Further, it would not be doing a good service to the insured to try to hold that an operation or other special service which it was dangerous for a considerable proportion of general practitioners to undertake was within the obligation. As regards the widening of the obligation to include some specialist services and not others, the witness said :—

(Q. 1089.) I suggest that when you come to the consideration of the whole of this subject, you will find, as has always appeared to us, that there is no half-way house between the completion of the service, to include everything that can be done outside residential institutions, and the necessity of making the kind of distinction that we have felt bound to draw.

The question of charging fees for special services was sharply distinguished from charging for treatment within the panel obligation.

(Q. 1100.) There would be no scamping the panel patient because he did not pay extra fees?—A. No. I will not say that no individual doctor would do so, but he would be repudiated by his colleagues. No doctor would justify such a proceeding I am sure.

Number of Doctors Engaged in the Service.

(Q. 1042-1048.) It appears from the evidence that approximately two-thirds of the practising general practitioners are on the panel, the estimated number being stated as 12,000 out of 18,000. In the mainly industrial boroughs the number of doctors on the panel is nearly 100 per cent. This is so, for example, in Walsall, West Bromwich, Dudley, Burnley, Rochdale, and Wigan. When one comes to bigger cities, such as Birmingham and Sheffield, which both have medical schools, there is a larger proportion of consultants and of border-line men who are partly general practitioners and partly consultants. These do not tend to come on the panel. For Birmingham the proportion is 65 per cent., and for Sheffield it is 66 per cent. Taking the county areas the proportion is rather smaller. In Devonshire there are only 54 per cent., in Cambridge it drops to 41 per cent., and in Kent 61 per cent. In the purely industrial areas it is difficult for a man to make any kind of living as a general practitioner unless he does go on the panel. The percentage is much lower in places like Bournemouth and Torquay.

Quality of the Service.

(Q. 1051.) The witnesses were questioned as to the statements frequently made that the services rendered by a panel doctor to his patients are different in character and inferior in quality from the services that he would render ordinarily to paying patients in the same economic circumstances. The reply was that—

In the great majority of areas there was no attempt whatever to discriminate between the insured and the non-insured; indeed, if there is any discrimination it is probably in favour of the insured, because a doctor would know that if he has to make a choice between two patients and he fails to respond to the call of the insured man he may find himself involved in a complaint.

Areas in which this could not be said confidently of panel practice were probably West-End and other well-to-do districts, where some doctors went on the panel, for example, to treat domestic servants in order that some other practitioner might not get a footing in the house. These doctors do not find it worth while to familiarise themselves with the Regulations, and they may render their services reluctantly.

An Increased Sense of Responsibility.

(Q. 1054.) Asked how the present service compares with the friendly society services before the Insurance Act, Dr. Smith Whitaker said, looking at the broad features of the two systems :—

The first thing that strikes me about the present insurance service is that it is under public control, and that the free wind of publicity blows through all the arrangements.

The doctor's contract is clearly defined, whereas in the case of club practice it was very often not clearly defined; in fact, it was almost the exception for a club to have a clearly drawn-up agreement with the doctors themselves, they having had every opportunity of expressing an opinion.

The witness then referred to the increased sense of responsibility for the service not only by the individual doctor but by the profession collectively, attributable largely to the provisions made in the Insurance Acts for direct participation by the medical profession in the administration of the Acts. By reason of public control, free choice of doctor, and the collective responsibility which the doctors have accepted for the efficiency of the system, there was a great improvement over anything that existed before the Insurance Acts.

Marked Decline in Sickness Benefit.

(Q. 1137.) At a later stage Dr. Smith Whitaker substantially repeated what he said above as to the improved service and its causes. He also quoted "one of the most experienced and most highly respected practitioners on the Tyneside" as saying that in recent epidemics he had become convinced that the insured suffered less severely than the uninsured, because they were not deterred by the same considerations from consulting the doctor as soon as they began to feel ill. They were taken in hand from the beginning.

This was in reply to a question from Sir Alfred Watson, the Government Actuary, containing the interesting statement that he had noticed a very marked decline in the sickness benefit claims of approved societies compared with the standard employed, which is based upon friendly society experience, and asked for an opinion whether the improvement in the medical service was a factor in the drop in the claims to which he referred.

(To be continued).

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Government and the Birth-Rate.

THE National Alliance for the Increase of the Birth-rate in France has supplied to the Government, at the latter's request, some figures with regard to the birth-rate question, in order to assist the Government in framing laws and regulations to protect large families and to provide for the care of children. Some of the figures furnished are of particular interest, and reveal rather an alarming future for the population of France. In order to maintain constant the active population (that is, the number of individuals between the ages of 20 and 60) 900,000 babies must be born in France each year. At present the number of births per year does not exceed 750,000. As the number of marriages annually may remain for some considerable time at about 300,000, then each young couple must produce at least three children, as was the rule up to 1896. Various schemes are therefore suggested to encourage the production of large families, such as lowering rates and taxes for large families and extracting contributions from families of less than three children towards a national birth fund; giving special facilities to large families in housing matters, instituting a "family vote," and providing insurance for widows and orphans.

A Valuable Sign of Death.

Dr. Icard, of Marseilles, who has published several articles on the signs of somatic death, has just devised a new method of establishing satisfactorily the passing of life from a body. The method consists simply in aspirating the serum from the subcutaneous tissue by means of a cotton thread used as a seton, and then examining the serum to see whether it is acid or alkaline. The tissue fluid is alkaline during life and becomes acid after death, turning alkaline later when the cadaver reaches the stage of ammonical putrefaction. The turning point from alkalinity is

constant and occurs early, taking place about six or seven hours after death, varying slightly in time according as the conditions in the body hasten or retard putrefaction. The author holds that the acidity of the cadaver is one of the stages of putrefaction. Whatever be the cause, the change itself he holds to be an absolutely certain sign of death, as certain as definite putrefaction, of which it is, in some way, the precursory indication. This method is very easy and the technique is of the simplest, as the only requirements are a needle and thread and two pieces of litmus paper, red and blue.

A New Academician.

To fill the vacancy in the Section of Surgery caused by the death of Dr. Eugène Rochard, the Academy of Medicine has recently elected Dr. Mauclore to its membership. Dr. Mauclore was born in 1863, and after a distinguished student career became surgeon to the hospitals in 1897 and *agrégé* professor to the Faculty of Medicine of Paris in 1898. He has been President of the Society of Pædiatrics and of the Society of Surgery. He has published many works on almost all branches of surgery, specialising more particularly in bone surgery. He has also devoted much special study to surgical tuberculosis, malformations of the vertebral columns and osteomyelitis. In 1917 he published a book entitled "Surgery of the War," and in 1922 an authoritative work on surgical grafts.

The Control of Private Laboratories.

Mistakes made in analyses conducted by private laboratories may result in serious consequences, and to reduce such possibilities of error to a minimum the Academy of Medicine proposes some measure of general control and registration of all private laboratories which undertake biological or pathological analyses for the public. The Academy therefore requested the Minister of Public Instruction to appoint a commission consisting of representatives of the Faculties of Medicine and of Pharmacy respectively, in order to draw up a curriculum of instruction to be given by the two faculties. At the conclusion of the curriculum three certificates would be granted, one in histopathology, one in chemical pathology, and one in bacteriology. In future one or more of these certificates will be required from any person who intends to conduct a medical analytical laboratory.

The National Bureau of Social Hygiene.

There has been established in Paris by recent legislation a branch of the public health service which has been named the National Bureau of Social Hygiene (Office National d'Hygiène Social). It is under the control of the Minister of Public Hygiene. The objects of this bureau are (1) to collect and publish statistics referring to the sanitary condition of France; (2) to centralise and render available for the national and local public services, the medical profession, the public health officers, and the public, all French and foreign publications and information relative to hygiene, and to the prophylaxis of social diseases; (3) to instruct and stimulate the public in France and in the colonies on all aspects of hygiene and race preservation, by means of continuous and carefully planned propaganda; and (4) to ensure coöperation between public authorities and private enterprise with a view to correlating all efforts made towards the betterment of the public health.

The Hydro-Therapeutics Conference.

The fifth congress of inland and marine watering-places and climatic stations will be held in Paris from April 2nd to 4th. The questions for discussion will be: (1) special legislation for hydro-therapeutic centres; (2) organisation of study-tours to such centres; (3) organisation of a *Crédit Thermal*; (4) organisation of climatic stations; and (5) the protection of wells and springs. The general secretary of the congress is Dr. Victor Gardette, 3, rue Alexandre-de-Humboldt, Paris 14^e.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The Price of German Medical Books.

OUTSIDE Germany the complaint has been raised that the price of German scientific books is beyond the pockets of those for whom they are issued, and further that foreigners are charged even higher prices than German students. The suggestion of profiteering in these complaints was answered recently in the press by the president of the German Publishers' Association. He points out that similar complaints have been made with reference to the scientific literature of other countries also, and that the question is connected with the general depreciation of the currency throughout the continent. In Germany many scientific books are now actually cheaper than at the time of their publication before the war, and the publishers' profit on new books is smaller than formerly. As regards journals, the price of any one issue of a German paper is the same as that for a similar English journal. The higher prices formerly charged to foreign readers were a consequence of the daily depreciation of the German currency which induced the publishers to ask for payment in foreign money. Now that the German currency has been stabilised this is no longer the case and the prices are the same abroad as in Germany. It is noteworthy that translations of German books published abroad are often more expensive than the German original edition.

Treatment of Empyema by Rivanol.

Prof. Rosenstein recently read a paper to the Medical Society of Berlin on the treatment of empyema by rivanol without the usual resection of a rib. The method consists in the evacuation of the pus by a trocar and the injection of 50 to 200 g. of a 2 per cent. rivanol solution. This procedure is repeated three to four times at intervals of three days. The empyema is then encapsulated by adhesions of the layers of the pleura, the pus becomes sterile, and eventually the fever disappears. When this has taken place, a small incision between the ribs may be made to hasten the absorption of the pus, which, however, occurs without an incision, although somewhat later. Eighteen cases have been successfully treated in this way without a resection of a rib and in the majority of cases without an incision. The method is not indicated in empyema associated with gangrene of a lung, pyopneumothorax caused by a gunshot wound of the lungs, and with pulmonary tuberculosis. All other cases of empyema, especially those complicating influenza and pneumonia, are suitable for this treatment. Rivanol has also been successfully used in 300 cases of mastitis, where large incisions could be dispensed with by injections of the compound.

Death from Suffocation due to X Rays.

In a recent issue of *Strahlentherapie* Dr. Frick described a case where death had occurred after the administration of X rays for lupus of the neck with swelling of the cervical glands. The first application produced no reaction, but after the second application cedema of the glottis ensued, which led to suffocation, and finally to death. The post-mortem examination showed, apart from the cedema, a small cancer or tumour of the larynx in its first stage, which had not produced any symptoms during life. Early reactions from the application of X rays are not rare, and when the rays are directed to the cervical region swelling of the mucosa of the pharynx and of the larynx may be produced. Hoarseness occurring after the administration of the rays must be carefully observed, because it may be a symptom of commencing cedema of the glottis. In the above case the hidden cancer of the larynx may have contributed to the fatal cedema.

Medical Members of the German Parliament.

In the recently elected German Parliament the medical profession is represented by four medical men and one medical woman. One of them, Dr. Bainsdorf, belonging to the Bavarian People's Party, distinguished himself as the administrative head of the Palatinate during the Separatist riots when all the leading Government officials had been removed from their offices and partly exiled by the French. Two medical members belong to the National Party, including Dr. Hedenkamp, who is the editor of the *Aerztliche Mitteilungen*, the official organ of the Leipziger Verband, and two are members of the Socialist Party. In the Prussian Diet there are six medical members, two belonging to the Centre, two to the People's Party, one to the Socialist Party, and one to the National Party.

Public Health Services.

HOSPITAL NOTES.

THE SCOTTISH HOSPITAL INQUIRY.

THE Hospital Services Committee, which is investigating the extent and nature of the inadequacy of the hospital and ancillary services in Scotland, has now taken evidence from the northern part of the country which shows that, generally speaking, the conditions in the Highlands are unsatisfactory. Geographically and financially, Scotland is divided to a greater extent than is England or Wales, and it was one of the proposals of Sir George Beatson, when giving his evidence as a witness, that Scotland, for the purpose of more efficient hospital administration, should be divided into four districts. Under this scheme each district would have its central hospitals with their auxiliary or recovery hospitals, and a clearing house in each district would be appointed under a commissioner for the distribution of patients.

Dr. G. Dick, medical officer of health for Caithness, said that provision was adequate for infectious diseases, but not for cases of general illness; only about 8 per cent. of admissions to hospital were medical cases. A central hospital would, however, be impossible without State grants and assistance from local authorities. It might be well to have a hospital ship for the Outer Islands and Orkney, particularly to serve the fishing population. Dr. Alexander Asher, of Thurso, declared that the accommodation in the wide area covered by his practice was most inadequate, and was accentuated by the limited space in working-class houses. There was clamant need for provision for surgical cases, and it was also desirable to find accommodation for maternity cases. New hospitals or auxiliary hospitals for Caithness would be unnecessary if the hospitals in Wick and Thurso were brought up to the modern standard of equipment and nursing.

Dr. K. Campbell gave similar testimony of inadequacy in the Oban area, which includes the Hebrides, and advocated lectures upon health, about which there was so much ignorance that he had even known people who were unaware of the locality of their stomach. Dr. J. Laurie, of Greenock, said that there was only one medical officer for the whole of the Greenock Infirmary, and "one man could not do all that work." There were six maternity beds, but there should be 20 or 30. The general hospital accommodation was insufficient, and the pressure could only be met by overcrowding the wards. The ideal hospital would provide for both paying and non-paying patients.

Dr. T. F. Dewar, of the Scottish Board of Health, said that for the most part the accommodation provided for the sick in the poorhouses of Scotland was substantially the same as when they were

erected in the middle of last century, and there would be great, if not insuperable, difficulties in the way of utilising them for the general sick without relation to destitution or social standing. By nothing short of radical conversion or practical rebuilding could they be made into efficient hospitals. The Poor-law hospitals proper were admirable and ready for conversion to general hospital purposes.

Evidence from Glasgow, Falkirk, Stirling, Dumfries, and Galloway showed that in each of those places hospitals were being enlarged or that extensions were contemplated. Mr. Robert Barclay, one of the directors of the Royal Hospital for Sick Children at Yorkhill, Glasgow, which he described as "the largest hospital devoted to children in the United Kingdom," said that the present enlargements would raise the accommodation from 275 to 350 cots. In addition to an enlarged admission and out-patient department, there would be orthopaedic, electrical, and milk departments, and a department for the manufacture of medical and surgical appliances, together with lecture-rooms; the accommodation at the country branch was, moreover, to be doubled. Mr. Barclay estimated the cost of these schemes at £100,000; £75,000 was appealed for four months ago and most of it had already been subscribed. He advocated the continuance of the voluntary system. If the paying principle were introduced a paying wing should be kept separate, and they should finance themselves. At present there are in Scotland three hospitals entirely devoted to children—in Edinburgh, Glasgow, and Aberdeen. Mr. James Thomson, representing the Glasgow Royal Maternity and Women's Hospital, said that although that institution had only 114 beds, there had been as many as 170 cases in the hospital at one time, and the average number of patients last year was 135.

Prof. John Glaister, of Glasgow, said that accommodation for surgical cases in that city was insufficient. The waiting lists on the surgical side were seriously swollen by adenoid and tonsil cases. The time had come to utilise the accommodation in the Poor-law hospitals, and auxiliary hospitals, erected and run on a paying basis at moderate cost to patients, would be a great boon to the middle classes. He was not in favour of the establishment of general hospitals by local authorities on the ground that their hands were sufficiently full with isolation hospitals, and that most of them had not yet made sufficient provision for the treatment of tuberculous surgical cases.

The Rev. Dr. J. Montgomery Campbell, representing the Dumfries and Galloway Royal Infirmary, was emphatically of opinion that the voluntary principle had proved its efficiency. It had an ethical as well as a practical value. It supplied, as rate-supported institutions never could, the human touch and the neighbourly office in the care and alleviation of sickness. The Dumfries Infirmary was at present meeting the demand, but the supply of beds had almost reached its limit; there are nominally 113 beds, and last year the average number of patients per day was 106.

Giving evidence as to hospital accommodation in the Falkirk district, Mr. W. J. Gibson, chairman of the managers of Falkirk Infirmary, said that they had been obliged to abandon taking paying patients because of the number of ordinary patients who had to be provided for. Outside the hospital there was no accommodation save in the people's homes, but there were many who would be glad of private accommodation. A site had been obtained for a new infirmary, and he thought there would be no difficulty in maintaining it, but the overlapping of appeals for subscriptions ought to be curtailed. The £5000 a year contributed to the Falkirk Infirmary was disproportionate to the £3000 raised in the same district for the Infirmarys of Edinburgh and Glasgow.—Ex-Provost Tomson, chairman of the managers, described the accommodation in Stirling Infirmary as "quite inadequate." It was intended to build an entirely new hospital at a cost of £70,000, and the interest of the people of the district was such that £26,000 was

subscribed towards that sum in six weeks. There is no present provision for maternity cases in Stirling, but the infirmary had undertaken to provide it.

BRITISH HOSPITAL FOR MOTHERS AND BABIES.—The Council for the Promotion of the Higher Training of Midwives is considering means of raising £40,000 to complete the British Hospitals for Mothers and Babies at Woolwich. Additions were made as recently as 1922, but the institution, which is amalgamated with the British Lying-in Hospital, founded in 1749, and the Home for Mothers and Babies, is still inadequate. Its special object is to provide a national training school for district midwives which will provide a training double as long as that usually given.

IMPROVING FORFAR INFIRMARY.—It is proposed to spend about £11,000 on alterations and improvements at Forfar Infirmary in addition to the extension work which is already in hand. Of this sum nearly £7000 will be devoted to a new nurses' block and kitchen. The hospital is seriously handicapped by lack of X ray facilities.

WESTMINSTER'S PRIVATE WARDS.—The private wards at Westminster Hospital are to bear the name of the Prince of Wales, and the new eye wards are to be called "The Wolfe Barry Wards" in memory of Sir John Wolfe Barry, who was chairman of the house committee for nearly 20 years.

£50,000 FOR NOTTINGHAM HOSPITAL.—Mr. W. G. Player has given £50,000 for the extension of Nottingham General Hospital. On previous occasions Mr. Player has given the hospital £10,000 as a war memorial fund and £5000 for the endowment of beds, while his brother, Mr. J. D. Player, is defraying the cost, amounting to between £30,000 and £40,000, of the enlargement of the Nottingham Children's Hospital.

HOSPITAL SATURDAY FUND GRANTS.—Grants amounting to £70,488 have been distributed among 230 hospitals and allied institutions. The largest total—£25,423—was given to special hospitals; the general hospitals were awarded £21,950.

NEW WARDS AT PRINCE OF WALES'S HOSPITAL, TOTTENHAM.—Two new emergency and observation wards are practically ready to be opened. The hospital serves a large industrial area full of factories and workshops and congested streets; accidents are consequently very numerous. King Edward's Hospital Fund has promised £1000 towards completion and equipment on condition that a similar sum is raised by the institution, but at present only about half of that amount has been given. The Rubber Growers' Association has set an interesting precedent by laying the floors of the men's and women's wards with rubber as a gift.

PAYING PATIENTS IN POOR-LAW INFIRMARIES.—The Shoreditch Board of Guardians has appointed a committee to consider the practicability of receiving paying patients in its infirmary. It was stated that although the infirmary is so full owing to the large amount of illness in the borough that the placing of beds in the aisles of the wards is being considered, the workhouse is half empty, and it was suggested that it should also be used as a hospital.

MANCHESTER'S EFFORTS FOR CHARITIES.—Councillor Mathewson Watson, honorary secretary and chief organiser of the efforts on behalf of Manchester Charities, in a recent address gave an account of his experience and the success of the efforts made since 1914. Up to the present more than £350,000 had been raised in Manchester and district on behalf of St. Dunstan's and the National Institute for the Blind. Of that sum about £250,000 had been divided between St. Dunstan's and other institutions for the blind in Lancashire. Henshaw's Blind Asylum in Manchester

had received over £20,000. For the King's Fund for Disabled Soldiers and Sailors Manchester raised £70,000, about £25,000 more than any other provincial town. For the Princess Mary Fund for the Nursing Association of Manchester £12,000 were collected. For the Prince of Wales's Boy Scout Fund £3000 and for the "White Heather Fund" nearly £30,000 were collected, and £40,000 for the Red Cross Fund. The Lord Mayor's Two Million Shillings Fund realised 1,466,000 shillings, sufficient to clear off the debts of the local hospitals—altogether about three-quarters of a million pounds since 1914.

AN AMERICAN SCHOOL OF HOSPITAL NURSING.—The Henry Ford School of Nursing and Hygiene and the Clara Ford Nurses' Home have just been added to the Henry Ford Hospital at Detroit, which is now one of the largest general hospitals in the world. The Nurses' Home contains 325 bed-sitting rooms, each with its own bath, and the building has been furnished in the English style, with more than 800 reproductions of famous paintings on the walls. There are dining-rooms, a tea-room, a library, and a lounge, and each nurse has her own letter-box. The School of Nursing has "handball courts" and a swimming bath, biological, chemical, and bacteriological laboratories, and a reference library. There is an auditorium which will seat 700 persons, with a stage and dressing-rooms and equipment for showing motion pictures. The course of instruction will last for two years and four months and, in addition to its technical side, will include music, art, literature, domestic science, athletics, and public speaking. There is said to be a long waiting list of young women of the highest type who, in addition to free board and lodging, will receive 10s. a week for pocket money during the first year and 12s. 6d. a week afterwards. The Henry Ford Hospital, which is a teaching institution, has a staff of nearly 100 whole-time medical officers.

HOSPITAL EXTENSIONS.—It is proposed to extend the Hartlepool Hospital at a cost estimated at between £10,000 and £20,000.—Work is about to start upon extensions of the Batley and District Hospital which will cost £24,000.

WAR MEMORIAL HOSPITAL AT NEWTON-IN-MAKERFIELD.—On a site given by Lord Newton a cottage hospital in memory of the fallen of Newton-in-Makerfield, and costing £9000, was formally opened on Jan. 10th. For building and general purposes £5000 were contributed by the governors of the hospital; a bequest from the late Mr. Robert Stone included £1000 for the hospital and a similar amount for the endowment fund; Mr. C. E. Turner gave £1000; the Vulcan Foundry, Ltd., £5000; the Bazaar of the Foundry yielded £1300; Sir William Collinwood gave £500; Messrs. Greenall, Whitley and Co., £500; and the wife and son of the late Mr. Thomas Vicars gave £1000 for the endowment of two beds.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 24TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely: small-pox, 147; scarlet fever, 1886; diphtheria, 1123; enteric fever, 31; pneumonia, 1356; puerperal fever, 53; cerebro-spinal fever, 6; acute poliomyelitis, 9; acute polio-encephalitis, 3; encephalitis lethargica, 65; dysentery, 7; ophthalmia neonatorum, 133. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases again exceeded 100, the increase being chiefly accounted for by 65 additional cases notified from Middlesbrough (C.B.), 16 from Derby (C.B.), 20 from Chesterfield (B. and R.D.), and 16 from a group of boroughs and urban districts in Notts.

Deaths.—In the aggregate of great towns including London, there were 2 deaths from enteric fever, none from small-pox, 9 from scarlet fever, 42 from diphtheria, 62 from measles, 195 from influenza, as compared with 142, 124, 100, and 83 in the four preceding weeks. In London itself the deaths from diphtheria numbered 12 and from whooping-cough 44.

Correspondence.

"Audi alteram partem."

THE DIAGNOSIS OF ACUTE DRUNKENNESS.

To the Editor of THE LANCET.

SIR,—I welcome the criticisms of Sir Charles Ballance and Dr. Maurice Cassidy, the chief surgeon and chief physician respectively to the metropolitan police, on the subject of my modest address on drunkenness.

I am gratified that it afforded them "interest and amusement." But it is evident that their interest must have flagged before they reached the end of my address, otherwise they would have noted that, so far from decrying the skill or independence of the medical officers of police, I specifically stated my firm belief that in cases where there seemed any uncertainty as to a prisoner's sobriety, the medical officer ought to, and as a matter of fact generally does, give the prisoner the benefit of the doubt.

Sir Charles Ballance and his colleague are disappointed that the address had so little to offer in the way of new signs or symptoms of drunkenness, apart from a suggestion as to examination of the cerebro-spinal fluid. I must, indeed, have failed in my exposition when I tried to point out that the so-called signs of alcoholic disability of the central nervous system, whether cerebral, cerebellar, pontobulbar, or otherwise, can each of them, individually, be produced by many causes other than alcoholic intoxication. This craving for a new sign implies a total misapprehension of the lesson I wished to convey. St. Paul remarked to the Corinthians that "the Jews require a sign, but the Greeks seek after wisdom." I should have expected Sir Charles Ballance and Dr. Cassidy, on this occasion at any rate, to be amongst the Greeks.

It is still more surprising to find that my distinguished critics range themselves alongside the medical officer who, at the discussion which followed my address, vigorously expressed his view that it was "a grave responsibility to differ from the opinion of a police surgeon." I agree. But it may at times be our duty to take that responsibility, rather than assent to a sober man being unjustly convicted of drunkenness.

If all police surgeons actually conformed to the standard of clinical examination carried out by Sir Charles Ballance and Dr. Cassidy, the percentage of errors, small as it is, would be still lower. Some police surgeons tell me that in a doubtful case they habitually spend half an hour or longer in their clinical examination of the prisoner. These are medical officers from whom one would be very chary in differing. But there are others. I personally know of cases where a perfunctory examination of a few seconds is all that the prisoner gets. The police surgeon smells the man's breath, tells him to walk along a straight line and back, looks at his pupils (!), and then says, "You are drunk"! No doubt in nine cases out of ten, in spite of this crude examination, he happens to be right. But I cannot but be sorry for any sober citizen who may happen to fall into the hands of such a medical officer, if he meets him "professionally" at a police station after dinner.

My statement that medical officers differ widely in their susceptibility to suggestion on the part of police constables is so conspicuously accurate as to be almost a truism. So long as medical officers are human beings, so long will they share this human characteristic. In youth, my Presbyterian up-bringing prevented me from accepting the dogma of Papal infallibility and now, at my time of life, I am not likely to subscribe to this new dogma of the infallibility of police medical officers, good as they are. And so I stick to my guns, inwardly comforted by

the solace of feeling that Sir Charles Ballance and Dr. Cassidy are really in agreement with me after all.

I am, Sir, yours faithfully,

J. PURVES-STEWART.

Buckingham-street, Victoria, S.W., Feb. 2nd, 1925.

PS.—I have also much enjoyed their jocund reminiscences of the bump supper.

CORRECT POSTURE.

To the Editor of THE LANCET.

SIR,—With reference to your remarks on this subject and the article on the Treatment of Postural Defects in Children by Mr. Muirhead Little in THE LANCET for Jan. 24th, I think that it would be an advantage to the public if more attention were given in schools to the question of posture before any defects arise. Physical exercises of some kind are taught in all schools both elementary, secondary, and private, but there does not seem to be any uniformity of opinion as to what is the best method for securing good balance and poise. I venture to suggest that the combination of strength with grace, which is presumably the athletic ideal, will never be acquired by means of physical drill or games alone, and that the question of dancing and rhythm must be introduced, as it is in the Dalcroze method in Geneva, or in the Margaret Morris dancing method in this country. The fact that dancing has a marked psychological effect is surely in its favour as a remedial or preventive measure.

I am, Sir, yours faithfully,

STELLA CHURCHILL, M.R.C.S.,

Chiswick, W., Jan. 31st, 1925. L.R.C.P., D.P.H.

AIR-EMBOLISM FOLLOWING URETHROSCOPY.

To the Editor of THE LANCET.

SIR,—I have read with interest the notes on cases of air-embolism following urethroscopy which appeared recently both in *The Lancet* and *British Medical Journal*. I quite agree with Prof. A. Fullerton in your issue of Jan. 31st that the "advantages of aero-urethroscopy are so obvious that there can be no question of abandoning it," especially as it is possible to reduce the risk to a minimum.

Some time ago I drew up the following rules for my own guidance in the matter: 1. Never do an air-distension urethroscopy on a patient who has had any instrument passed within the previous 48 hours. 2. If even the slightest bleeding followed the passage of this instrument, the interval should be increased to at least a week. 3. Never use air-distension in the presence of urethral hæmorrhage. 4. If the urethroscope causes the slightest bleeding, withdraw it at once.

The majority of cases of air-embolism are due either to using the urethroscope to see why an ordinary bougie cannot be passed, or to persisting in the examination after bleeding has commenced. It is an interesting fact that, although the urethroscope is probably most frequently used in the treatment of chronic urethritis, air-embolism is practically confined to cases of stricture. In the former condition the urethral wall gives before the cannula of the urethroscope and is not injured; in the latter, it is inextensible and liable to abrasion. The greatest care should, therefore, be taken in examining these cases. The cannula should fit the meatus easily, and should slip down the urethra by its own weight. When its progress is arrested, no attempt should be made to pass it further, as this usually causes an abrasion of the urethral wall. The obturator should then be removed, the tube swabbed out, the urethroscope applied, and the light switched on. Air is then cautiously admitted and the examination made. Bleeding usually occurs from a wide-calibre stricture, situated in front of the main one, which is injured during the passage of the cannula.

I think that many of the old cases of so-called urethral shock were really cases of air-embolism. At the post-mortem examination the presence of air in the heart may easily be missed, unless the great

vessels are tied off, and the heart removed and opened *under water*, just as one looks for punctures in the tube of a pneumatic tyre. This, I believe, was rarely done in cases where death followed urethroscopy. Prof. Fullerton wonders if urethral shock ever occurs; I think it does, but it is very rare. I do not accept as urethral shock cases where either cocaine or air-distension has been used, as in the non-fatal cases it is practically impossible to exclude an idiosyncrasy to the drug, or a mild degree of air-embolism. A case occurred while I was house surgeon at St. Peter's Hospital, which I believe was one of true urethral shock. A man of about 50 presented himself at the out-patient department complaining of symptoms suggestive of stricture. The surgeon in charge passed a straight metal bougie about an inch down the urethra in order to measure the size of his meatus preparatory to urethroscopy. The patient suddenly sat up on the couch with dilated pupils and gasping respiration, and in less than half a minute fell back dead. In this case no local anaesthetic and no air-distension were employed.

I have had two non-fatal cases of air-embolism in my own practice, in one of which I noticed definite surgical emphysema of the perineum. They were both suffering from stricture, for which many instruments have since been passed.

I am, Sir, yours faithfully,

Harley-street, W., Jan. 31st, 1925. J. SWIFT JOLY.

THE SALE OF PATENT MEDICINES.

To the Editor of THE LANCET.

SIR,—I am exceedingly glad that THE LANCET has once more offered its powerful aid to promote legislation in the interest of the health of the people. The republication of the report of the Select Committee of the House of Commons on the Sale of Patent Medicines of 1914 and of the text of the Proprietary Medicines Bill of 1920 has again brought into prominence the urgent need for the legislature to protect the public from exploitation by the unscrupulous nostrum-monger. The facts are so well established that it is unnecessary to adduce additional proof that many of these secret so-called remedies may do positive harm by their noxious ingredients or negative harm by leading to delay in the recognition of serious disease.

The Bill in clause v., para. 2, suggests certain valuable safeguards with regard to the registration of proprietary remedies, but curiously omits any regulation to secure constancy of composition or to guarantee dispensing by a person possessing some knowledge of the art. Furthermore, some protection of the doctors themselves seems necessary against the samples chiefly from abroad, accompanied by much plausible pseudo-scientific literature, with which they are pestered, and may at times be deluded.

Recently I had brought to me an alleged colloidal solution of ozone with much literature stating that it was a specific for consumption. On analysis it was found to contain 46 per cent. absolute alcohol, a little free hydrochloric acid, a trace of an essential oil, probably oil of lemon, and a doubtful trace of hydrogen peroxide. Evidence of the presence of ozone in any appreciable quantity was not forthcoming, and even if it were present, there do not seem to be any grounds for the assertion that it is specifically inimical to the tubercle bacillus. Seeing that free hydrochloric acid was present, the statement that when mixed with potassium iodide it would turn starch-paste blue did not seem to prove conclusively the presence of ozone. This is but one example where the claims were so plausible that I went to the length of having a sample analysed. The law on the sale of patent medicines in other countries seems to have prevented the unscrupulous from approaching the public directly, and in consequence, with a cunning worthy of a better cause, they have set insidious traps for the doctors.

Finally, it would seem consistent with its dignity for the medical profession to point out to those whom

it may concern that recommendation for public honours should not be made for those who have achieved wealth and notoriety by selling worthless nostrums to a credulous public, even though they may have salved their consciences by munificent benefactions.

I am, Sir, yours faithfully,
Cavendish-place, W., Jan. 31st, 1925. CECIL WALL.

PERNICIOUS ANÆMIA, SPRUE, AND THE ENTERIC GROUP.

To the Editor of THE LANCET.

SIR,—If pernicious anæmia and sprue present indistinguishable blood-pictures, then a case of mine which may connect this anæmia with the enteric group deserves to be considered. A girl, aged 23, who died of pernicious anæmia, exhibited the Widal reaction in such dilutions as to make it extremely probable that she had typhoid fever. The course of the case showed that this was not so, but that there was a very rapidly fatal anæmia. This case occurred about 14 years ago. I have since suggested: (1) That it should be ascertained if enteric fevers or T.A.B. vaccine protected even temporarily from pernicious anæmia; (2) that T.A.B. vaccine might be given to persons suffering from pernicious anæmia during their first temporary recovery.

Are there records of any person with a recent history of enteric fever, or recent injection of vaccine developing pernicious anæmia? Anyway, if Dr. C. Elders's conclusions in your issue of Jan. 10th are correct, I have had a case of rapidly fatal pernicious anæmia, which had the blood-picture of sprue and the blood reaction of typhoid fever.

I am, Sir, yours faithfully,

PERCY GULLY, M.R.C.S., L.R.C.P.
Bordon, Hants, Jan. 30th, 1925.

EXTENSOR PLANTAR RESPONSE DUE TO MORPHIA.

To the Editor of THE LANCET.

SIR,—Prof. T. R. Elliott and Dr. F. M. R. Walshe, in a recent paper (THE LANCET, Jan. 10th, p. 65) on the plantar response in certain toxic states, say that "Opium poisoning has apparently not yet been observed to lead to an extensor response." It will therefore be of interest to record this observation, made about six months ago, of the temporary appearance of a double extensor plantar response in a patient who was deeply under the influence of morphia.

A woman of 70 was suffering agonising pain which was discovered later to be due to a malignant metastatic growth in the femur. She was given 1 c.cm. of omopon hypodermically with no effect. About half an hour later morphine hydrochloride, gr. $\frac{1}{2}$, was injected and 25 minutes after, as the pain was still extreme, a further dose of morphine hydrochloride, gr. $\frac{1}{2}$, was given in the same way. She was examined some two hours after the last injection. She was then in a deep stupor; her respiration-rate was about 8 per minute; she gave a very definite extensor plantar response on both sides; there were no other signs of pyramidal disease. This state of stupor continued for about 18 hours. About 22 hours after the administration of the drug she was awake and able to answer questions. The plantar reflexes were tested and found to give a flexor response on both sides.

It will be noted that this patient had had probably as much morphia as could have been given her with safety, but her condition under the drug was not such as to give rise to anxiety. In the paper already quoted the occurrence of an extensor plantar response during very deep sleep is referred to. This should make one prepared to find the like in subjects sleeping or stuporose under the influence of any hypnotic drug. It is likely that the phenomenon will be observed more frequently now that attention has been directed to it.

I am, Sir, yours faithfully,

G. M. KENDALL, M.B., M.R.C.P.
Epsom, Jan. 22nd, 1925.

THE DIAGNOSIS OF APPENDICITIS.

To the Editor of THE LANCET.

SIR,—I have read Mr. Rendle Short's clinical lectures on appendicitis (Part I.), in *THE LANCET* of Jan. 31st, and especially that part relating to diagnosis, with much interest, but it appears to me to show that even when conclusions are drawn from the vast amount of clinical material he had to work with exceptions are bound to be met with, and it is usually the exceptions which give rise to our real difficulties.

I have had several well-marked cases of appendicitis in which pain was quite definitely not the first sign. One of these occurred in my wife, who is also a member of the medical profession. She went to bed one night apparently perfectly well and developed severe vomiting and diarrhoea during the night, but was quite free from abdominal pain until about 9 o'clock next morning. As the day progressed she developed typical signs of appendicitis and was operated on the same evening. Another case of mine in which vomiting was the first symptom, and preceded the onset of pain by some hours, occurred in a child of 11 years old.

I have been impressed with the number of cases I have seen recently where operation has revealed a severe appendicular lesion, in spite of the fact that the patient had a normal temperature and pulse-rate. One such case was in a woman five months pregnant, where operation revealed an appendix on the point of perforation.

Another recent case of mine has several interesting features. My wife and I attended a multipara in her sixth confinement, knowing that she had had severe post-partum hæmorrhage in her last confinements. The labour was conducted without any vaginal examination being made, and the patient did well for about 36 hours, when she collapsed. She had evidently had a severe intra-uterine hæmorrhage with very little external loss, and we gave her a hot intra-uterine douche under general anaesthesia. Following this her course was uneventful until the fifth day, when she complained of pain in the region of the right iliac fossa and diarrhoea. Examination revealed marked tenderness over the appendix region and much tympanitic abdominal distension. Her uterus was palpable on the left side firmly contracted down, and her lochia were quite normal. A tender swelling could be felt in the right lateral fornix. We diagnosed acute appendicitis after a certain hesitancy on account of her puerperal condition, and advised her removal to hospital. Unfortunately she absolutely refused this until 72 hours later, by which time she was desperately ill with an obvious infection of her general peritoneal cavity. At the operation general peritonitis was found with much free fluid and a perforated appendix. Her ovaries and tubes showed no abnormality, but she had a fibroid uterus which would explain her tendency to hæmorrhages. It was interesting to note that the fluid in her peritoneal cavity was of a clear yellowish-green colour, and quite free from the usual faecal odour of such cases, but unfortunately no bacteriological examination was made. The woman's condition was most critical for a few days. She is now slowly recovering, but her wound has not yet healed.

I am, Sir, yours faithfully,

W. A. WHITEHOUSE PARKES, M.B., M.R.C.S.

Stourport, Feb. 2nd, 1925.

INFANT FEEDING.

To the Editor of THE LANCET.

SIR,—I was interested to read in your issue of to-day's date the report of their study by Dr. Donald Paterson and Dr. Ruth Darby, in which they state that a thriving infant should receive $2\frac{1}{4}$ to $2\frac{3}{4}$ oz. of breast milk (or its equivalent) per lb. weight per day. This sounds all right for a child up to 10 or 12 lb., but they do not say whether this is to be

carried on with a child weighing 20 lb. If not, how much is he to have? Obviously you cannot give him 50 oz. of milk in a day!

I am, Sir, yours faithfully,

MARIE C. STOPES.

Givons Grove, Leatherhead, Surrey, Jan. 31st, 1925.

THE RESIGNATION OF HOSPITAL APPOINTMENTS.

To the Editor of THE LANCET.

SIR,—In an annotation on the resignation of a distinguished professor of surgery you comment approvingly on his resolve to withdraw from private practice simultaneously with his resignation of his university and hospital appointments. You go on to say, "His professional colleagues will recognise that this is the action of a single-minded man, who has resolved that he will not create leisure in which to discharge private work by the easy process of giving up honorary or official duties." In this I think you display less than your usual temperate attitude. Members of hospital staffs submit to many restrictions and self-denying ordinances which are doubtless necessary and salutary, but here you touch on a matter which must be left to the individual. You must remember that many men are reaching the retiring age whose normal time of harvest has been seriously affected by the war and the subsequent heavy taxation; some of them come under an earlier superannuation rule than their predecessors, which means both delayed promotion and accelerated retirement. But apart from the financial aspect, resignation of private practice, although a relief to some, would deprive others of their chief interest in life. Again, a man may feel that the time has come to entrust official duties to his juniors, but is less likely to do so if this involves complete retirement. I should strongly deprecate any pressure being put upon him to enforce this.

I am, Sir, yours faithfully,

Feb. 2nd, 1925.

HOSPITAL PHYSICIAN.

*** "Hospital Physician" is criticising an attitude which it was not intended to assume, but the construction put upon the words is perfectly fair. It was not intended, however, that they should be used with so general an application. Every man must judge for himself what his course of conduct is to be, and circumstances will operate in different directions in different cases. We had in mind the position where institutions have felt, to our knowledge, the withdrawal of valued names when they considered that support might have been continued in spite of the exigencies of personal work.—ED. L.

AMBULANCE COÖRDINATION.

To the Editor of THE LANCET.

SIR,—With regard to the question of ambulances and accidents discussed in an article in *THE LANCET* of Jan 17th, and in which laymen are at least equally interested with the medical profession, I venture to suggest that *THE LANCET* might bring influence to bear with a view to securing coördination of the four public ambulance authorities to which reference is made. At any rate, there should be agreement between those authorities which would leave to the London County Council responsibility for the collection and removal to hospitals of cases of accident or sudden illness in streets and other public places when summoned by the police. A convenient and natural (if not too strictly enforced) division of duties would leave cases of accident or illness in houses to the care of the Metropolitan Asylums Board, possibly with the coöperation of ambulances supplied by the St. John Ambulance Association and the Red Cross Society. I have been informed that the Metropolitan Asylums Board would not be unwilling to partake if well-defined and limited duties were assigned to them.

A difficulty might arise occasionally, as in cases of sudden need through accident in a house, where delay might arise through the strict application of such a system as I have suggested above. This points to the assigning of a certain amount of discretion to the police, or to a central authority presiding over the whole system. Whether this would involve difficulties between such bodies as the Home Office, the Ministry of Health, and the County Council would best be brought out at the joint conference, which is evidently needed if anything is to be done, and at which, no doubt, the hospitals and infirmaries would expect to be represented.

With regard to the present scanty supply of ambulances for accidents, it seems to me that it should be possible to place the control and upkeep of these, or the major part of both, upon the County Council, leaving the provision of them, or the major part of it, to the borough councils who should be the best judges of the needs of their districts, and should also be responsible for the original provision of house room for them, whether by voluntary subscription from the public, for whose benefit they would be provided, or from the rates. At any rate, neither 10 nor 13 ambulances can be enough for the County of London, if all, or most, of the unfortunate persons who meet with accidents are to be given a fair chance of prompt treatment.—I am, Sir, yours faithfully,

London, Jan. 26th, 1925.

E. A. ARMSTRONG.

"ELECTRONIC REACTIONS."

To the Editor of THE LANCET.

SIR,—As President of one of the two sections of the Royal Society of Medicine, under whose ægis the preliminary communication of Sir Thomas Horder was made, it might not be out of place for me to write. In so doing I have no desire to be drawn into any controversy.

The attitude of the Section of Electro-Therapeutics was strictly impartial and non-committal. We live, fortunately, in the twentieth century, a century in which any suggestion, however fantastic or impossible it may appear at first sight, is sure of a fair and reasonable hearing. In this respect we are far better than were our forbears. In reading, as I did with great care, the full report of the committee of the *Scientific American*, it failed to bring any sense of conviction to my mind. It appeared to me to be peevish, unscientific, and inchoate. No special investigation appeared to have been attempted, and the report bore the mark of a confession of failure—failure to find any one of the persons using the original Abrams box (or, indeed, any of the 50 or more improvements) able or willing to submit to tests, the latter not always suggested from any true scientific standpoint.

The communication of Sir Thomas Horder made many points very clear, and it may be well to emphasise them. It was definitely stated:—

1. That the communication was no more than a preliminary report of research.
2. That there was no implied or possible sanction for the use of any apparatus bearing the name of Abrams (including the emanometer of Boyd) for the diagnosis or treatment of disease.
3. That, assuming the probability of there being some purely physical basis for electronic reactions, no practitioner (and this naturally included Dr. Boyd himself) had any justification for using any form of apparatus in any way other than in laboratory research.

If anything in Sir Thomas Horder's communication by any possible stretch of imagination could be held to have given any sanction to the gross pretensions of the "E.R.A." practitioner or could have encouraged the public, I can only say that there must be something very amiss with my mentality.

I am, Sir, yours faithfully,

Feb. 2nd, 1925.

STANLEY MELVILLE.

Obituary.

GEORGE COOKE ATTFIELD, M.R.C.S. ENG.

Dr. George Cooke Attfield, whose remains were cremated at Norwood on Jan. 20th, was believed to be the oldest medical man in the country.

Born at Bath on Jan. 27th, 1826, a son of the Rev. W. Attfield, he intended to take up either a military or naval career, but as his father raised objection he turned his attention to medicine and entered as a student at St. Bartholomew's Hospital. He qualified M.R.C.S. in 1850, so long ago that he had been affectionately described as the "Father of Bart.'s," and for four years he was associated closely with Sir James Paget and Sir William Lawrence. A keen sportsman, with cricket as his foremost love, he played for Somersetshire and Surrey, being wicket-keeper for the latter county. He was invited to join an All-England XI. to Australia, but his medical duties prevented him from accepting. It was not long after, however, that he did proceed to Australia. He accepted an appointment under the Government as Chief Medical Officer of Prison Settlements in Western Australia, which work he continued until their abolition in 1879. He married the youngest daughter of the late Sir John Roe, then Surveyor-General of Western Australia. He retired soon after his return to this country, and settled in Buckingham-road, Brighton, afterwards moving to Salisbury-road, Hove, where he died on Jan. 16th in his ninety-ninth year.

Attfield possessed a winning and gracious personality. He made many friends both in Brighton and the sister town of Hove, where in spite of his years he continued to live a very active life. In games of all sorts he took a great interest, but his chief recreation was billiards, and at his club at Hove he marked his eighty-seventh birthday by making a break of 87. Only during the last few years—since the war—did his great age begin to tell upon him, but his senses were wonderfully acute right to the last. Dr. F. J. Paley, the well-known Hove practitioner, who died in November last, was a son-in-law of Dr. Attfield.

CHARLES JAMES LOWNDS, L.R.C.P. & S. EDIN., D.P.H. EDIN.

Dr. C. J. Lownds, of East London, Cape Province, South Africa, died in East London on Jan. 18th after an illness of 18 months, and at the age of 61. He was the second son of Thomas Lownds, of the Indian Medical Service, and was born at Rajputana in 1863. He graduated B.A. at Cambridge, and studied at Westminster Hospital, where he was Houldsworth Scholar, and at Edinburgh. He qualified in medicine in 1887, and after serving as ship's medical officer on voyages to China in 1889–90 commenced general practice in England. Eleven years later he went out to South Africa and became resident medical officer to the Frere Hospital, East London. He was a keen sportsman, a cricketer, an oarsman, and a golfer. He was returned on two occasions to represent the constituency in the Cape Provincial Council, and was highly esteemed both as doctor and citizen.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held on Thursday, Feb. 19th, at the Guildhall, Swansea, when discussions will take place on Maternity and Child Welfare, Smoke Abatement, and the Cardiac Cripple. The chair will be taken at 2.30 P.M. by Dr. Louis C. Parkes, Deputy Chairman of Council.—A sessional meeting will be held on Friday and Saturday, Feb. 20th and 21st, in the large theatre of the University, Edmund-street, Birmingham, when Prof. John Robertson, M.D., will open a discussion on Fresh Air in the Treatment and Prevention of Disease, and Dr. Cecil G. Teall will speak on Artificial Light in the Cure of Disease. The chair will be taken at 7.30 P.M. on Friday by Dr. Parkes.

The Services.

ROYAL ARMY MEDICAL CORPS.

THE following were successful at the recent competition for commissions in the R.A.M.C.: T. A. J. M. Dodd, M.B., B.Ch., Oxf. and St. Bart.'s; R. A. Bennett, M.B., Ch.B., Edin.; W. D. Speedy, M.B., B.Ch., Trinity Coll., Dublin; J. N. Atkinson, M.B., B.Ch., Trinity Coll., Dublin; W. A. D. Drummond, M.R.C.S. Eng., L.R.C.P. Lond., Univ. Coll., Dundee; J. D. Corner, M.B., Ch.B., Edin.; W. H. Carter, M.B., Ch.B., D.P.H., Edin.; J. G. E. Vachell, M.B., B.Ch., Camb. and St. George's; and J. T. Smyth, M.B., B.Ch., Queen's Univ., Belfast.

The undermentioned (retd. pay) Maj. are granted the rank of Lt.-Col.: T. H. Gibbon and R. E. Humfrey.

Maj. J. E. Hoar is placed on retd. pay.

Capt. C. V. Thornton and E. J. Mannix retire, receiving a gratuity.

MILITIA.

Capt. T. Hampson to be Maj.

TERRITORIAL DECORATIONS.

The King has conferred the Territorial Decoration upon Lt.-Col. (Bt. Col.) T. B. Wolstenholme and Maj. H. W. Read and E. Alderson.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby, Surg. Sub-Lt. B. W. C. Archer to be Surg. Sub-Lt.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flying Officers: H. C. Patterson and F. L. White. Flying Officer G. R. Nodwell is promoted to the rank of Flight Lt.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of Lt.-Col. H. Emslie-Smith.

Capt. (Actg. Maj.) W. E. Brierley relinquishes the acting rank of Maj.

Capt. Gokal Chand Sood relinquishes his temporary commission.

Medical News.

UNIVERSITY OF OXFORD.—In a Congregation held on Jan. 22nd, presided over by the Warden of All Souls College (Pro-Vice-Chancellor), the following Degrees in Medicine were conferred:—

Bachelor of Medicine.—Harold E. Harding, Oriel College; Allan W. Linford Row, Brasenose College; and Michael J. W. Minshall, Keble College.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Jan. 28th the Vice-Chancellor, Prof. E. A. Gardner, being in the chair, the following appointments were made: Mr. H. L. Eason, Member of the General Medical Council; Prof. H. R. Kenwood, Representative (in respect of University College) at the Congress of the Royal Sanitary Institute to be held at Edinburgh in July, 1925.

Lectures in Surgery.—A course of four advanced lectures in surgery on Some Practical Considerations and Experiences in the Conservative Treatment of Fractures of the Pelvis and the Lower Extremity will be given in the Medical and Surgical Theatre at St. Bartholomew's Hospital Medical College (West Smithfield, E.C.), by Sir William I. de Courcy Wheeler, at 5 P.M., on Feb. 16th, 17th, 18th, and 19th. At the first lecture the chair will be taken by Mr. Walter G. Spencer. The lectures, which will be illustrated with lantern slides, are addressed to students of the University and to others interested in the subject.

A lecture entitled the Relation of Paralysis Agitans to the Parkinsonian Syndrome of Epidemic Encephalitis will be given in the Lecture Hall of the Royal Society of Medicine, 1, Wimpole-street, W., by Dr. R. Cruchet, professor of pathology and general therapeutics in the University of Bordeaux, at 5 P.M., on Wednesday, Feb. 25th. The chair will be taken by Sir Humphry Rolleston. The lecture will be delivered in English and illustrated with lantern slides. Admission to all these lectures is free.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia of the College was held on Jan. 29th, the chair being occupied by the President, Sir Humphry Rolleston. The following candidates having passed the required examination were admitted Members: Drs. Wallace W. Adamson, Wilfrid H. W. Attlee, Francis J. Benjamin, Frank Brockington, Charles R. Burns, Ernest N. Chamberlain, Sibyl R. J. Eastwood, Francis W. B. Fitchett, Calvert M. Gwillim, David M. Lloyd-Jones, Montague Maizels, Herbert V. Morlock, Bertram S. Nissé, Hilary J. Roche, George K. Stone, James A. Struthers, and Alfred Williams-Walker.

Licences to practise physic were granted to the following candidates who have passed the Final Examination of the Conjoint Board and have complied with the by-laws of the College:—

M. Abse, Cardiff and Univ. Coll.; J. D. Allen, St. Bart.'s; G. T. Allerton, London; C. A. Amesur, St. Thomas's; Kathleen J. Atkinson, King's Coll.; Margaret A. Bannerman, Royal Free; W. D. Beck, Birmingham; C. E. G. Beveridge, Oxford and St. Bart.'s; O. P. Bewers, St. George's; Anna M. V. Bonhote, King's Coll.; V. H. Boobbyer, St. Mary's; W. A. Bourne, Cambridge and St. Bart.'s; R. N. Brandwood, Guy's; S. Brest, H. F. Brewer, D. A. Briggs, and D. J. Brims, St. Bart.'s; R. J. Brocklehurst, Oxford and St. Bart.'s; T. H. P. Brooks, London; Margaret H. Brown, Charing Cross; W. A. Browne, Madras and St. Mary's; Olive B. Buckley, King's Coll.; W. H. Cameron, Toronto and Middlesex; A. F. Chalkley, Leeds; Gwendoline Chave, Royal Free and St. Mary's; H. F. Chillingworth, St. Bart.'s; G. F. Chissell, Middlesex; L. Chodorsky, Warsaw and St. George's; J. Chronnell, Manchester; H. A. Clegg, Cambridge and St. Bart.'s; A. V. Clemmey, Oxford and Guy's; Doris M. Collins, Royal Free; L. C. Cook, Cambridge and St. Thomas's; L. N. R. Comty, London; Margaret I. B. Cowling, Royal Free; C. P. Craggs, Durham and St. Bart.'s; Dorothy E. Crellin, Bristol; J. Currie, St. Bart.'s; M. Cutner, St. Mary's; Gweneth M. Daniel and Annie E. C. Davies, Westminster; A. L. Davies, Oxford and St. Thomas's; J. R. Davies, St. Thomas's; W. H. Davies, Westminster; A. R. Davison, Cape and St. Thomas's; Charlotta D. N. de Wilde, Royal Free and London; G. E. Ellis, St. Bart.'s; O. M. Ellis, Cardiff; Mary H. Elmitt, Royal Free; C. W. Evans, Univ. Coll.; J. Evans, Cardiff and Charing Cross; N. B. Farman, Charing Cross; J. T. Fathi, London; L. Fatti and C. F. Fernando, Univ. Coll.; M. G. Fitzgerald, Cambridge and St. Bart.'s; Dorothea C. Forbes, Royal Free and St. Mary's; G. R. Ford, Guy's; W. S. Fricker, Cardiff and King's Coll.; T. M. Frupp, Guy's; O. P. Giles, Birmingham; G. D. Gordon, Cambridge and St. Thomas's; H. W. Gordon, Cambridge and St. George's; R. A. Grant, Guy's; F. N. Green, Cambridge and Liverpool; A. L. Greenway, Calcutta and King's Coll.; D. L. Greig, Middlesex; J. M. Hall, King's Coll.; Constance I. Ham, Bristol; G. Hamada, Birmingham; J. E. S. Hamilton, Bristol; C. H. Hampshire, Univ. Coll.; A. W. Hanlon, Liverpool; Hans-Raj, King's Coll.; Irene D. F. C. Hastlow, Birmingham; N. H. R. Hatfield, Cambridge and St. Mary's; S. Helberg, Zurich and London; A. Helmy, Cairo and St. Thomas's; Freda K. Herbert, King's Coll.; E. Herzberg, Heidelberg and Univ. Coll.; A. E. Hill, Guy's; C. H. Hilliard, Cambridge and St. George's; Minnie E. Hope, Royal Free; E. C. Hudson and D. B. Hughes, London; Katherine E. W. Hulse, Charing Cross; O. R. Humphreys, Cardiff and London; F. S. Hunter, Birmingham and Bristol; O. L. Hutchinson, St. Andrews and London; Joy Hwa, Birmingham; S. Hyman, Leeds; Elizabeth Jacobs, St. Mary's; Kate D. James, Royal Free and St. Mary's; E. J. Jenkins, Birmingham; C. W. W. Jeremiah, Cardiff and Middlesex; D. F. Johnstone, Guy's; Dilys Jones, Westminster; L. A. Key, Cambridge and St. Thomas's; Caroline B. Kibble, Royal Free; C. T. Kitching and W. R. Kusel, Cape and St. Thomas's; Marjorie A. M. Lambert, Royal Free; G. S. Landon, Guy's; M. C. Lavin, London; H. Levy, Durham and St. Bart.'s; H. Lewis, Guy's; A. C. Liesching, St. Bart.'s; L. A. N. Line, Birmingham; W. H. G. M. Ling, Edinburgh and St. Mary's; Madeline R. Lockwood, Univ. Coll.; A. C. Lysaght, Bristol and Guy's; Catherine B. McArthur, Royal Free; S. McClements, King's Coll.; F. G. Macdonald, St. Thomas's; Dorothy F. McIntosh, Charing Cross; J. H. Macpherson, King's Coll.; Helena M. J. McQuaid, St. Mary's; R. G. Maliphant, Univ. Coll.; J. P. Marsden, Cambridge and St. Thomas's; G. R. Marshall, St. Mary's; E. L. Martin, Charing Cross; A. W. C. Mellor, Cambridge and St. Bart.'s; C. P. Miller, St. George's; F. C. Miller, Guy's; G. J. Morris, Cardiff and Middlesex; C. F. Morrison, Guy's; A. M. Murray, Middlesex; W. R. Nash, Cardiff and St. Bart.'s; Margaret I. Neal, London; E. L. Newell, Oxford and St. Thomas's; R. A. Newsom, King's Coll.; H. W. Nicholson, Cambridge and St. Thomas's; J. A. Noot, Cardiff; R. A. Norman, Guy's; J. N. D. O'Rafferty, Guy's; Evelyn D. Owen, Cardiff and Charing Cross; G. W. C. Parker, Cardiff and St. Bart.'s; A. E. Parkes, St. Bart.'s; W. Parry-Jones, London; R. Paton, Cardiff and Middlesex; V. Patrick, Manchester; F. L. Patterson, London; Gladys L. Pearson, Royal Free; A. D. Pegg, St. Thomas's; Gwyneth Matti Pennant, Cardiff and King's Coll.; H. C. Pierce, Cambridge and Liverpool; C. P. Pinckney, Cambridge and St. George's; C. J. Polson, Birmingham; L. W. Proger, Middlesex; D. C. Prowse, Bristol; R. S. Pyrah, Leeds; V. I. Raman, Madras and London; C. Rankin, Liverpool; M. D. Rawkins, St. Bart.'s; J. T. Rees, Cardiff; Olwen M. Richards, Cardiff and Charing Cross; J. T. C. Roberts, Liverpool; J. J. R. Robinson, St. Thomas's; Wemyss C. Robinson, King's

Coll.: G. F. Rowbotham, Manchester; Alysoun H. Rowntree, Royal Free; A. B. Ruffail, Cairo and King's Coll.; K. G. W. Saunders, St. Thomas's; S. D. Schultz, Manitoba and Middlesex; Claude E. Sharp, McGill and Univ. Coll.; T. A. Shaw, Guy's; Frances E. Smith, Charing Cross; Sylvia M. T. Smith, Bristol; A. D. Soares, Bombay; K. H. Southall, Univ. Coll.; I. P. Spurrell, Guy's; Ethel L. A. Stamborg, Royal Free; B. G. Staniland, London; Ruby O. Stern, Charing Cross; D. D. S. Stewart, King's Coll.; P. Subbaramayya, Madras and London; A. F. Taylor, St. Bart.'s; E. J. Thomas, Cardiff and St. Thomas's; J. D. S. Thomas, Guy's; W. S. Thomas, Univ. Coll.; E. Thompson, St. Thomas's; W. R. Thrower, St. Bart.'s; T. G. Tresidder, Guy's; E. A. Trim, Cambridge and St. Thomas's; V. C. Tughan, Univ. Coll.; Beatrice M. Upshon, Madras and Royal Free; L. C. D. van der Borcht, Ghent and Univ. Coll.; H. van der Post, Guy's; G. B. W. Walker, Cambridge and St. Mary's; R. A. Walsh and L. B. Ward, St. Bart.'s; Catherine Watterson, Univ. Coll.; H. V. Wells, Charing Cross; J. Whillis, Durham; F. L. White, London; C. R. Williams, Leeds and London; D. G. Williams, Cardiff and King's Coll.; E. R. Williams, Cardiff; H. H. Williams, Liverpool; D. A. Wilson, Middlesex; Emily A. C. Wilson, Charing Cross; H. M. Worth and C. L. Worthington, Guy's; Annie Yoffa, Cornell and Royal Free; G. C. Young, St. George's; and J. C. Young, Guy's.

Diplomas in the undermentioned subjects were granted, jointly with the Royal College of Surgeons of England, to the following candidates:—

DIPLOMA IN PUBLIC HEALTH.

Dora M. Berry, John Bevan-Jones, Hilda A. Bond, and Norman Briggs, Univ. Coll.; William H. Brodie, Aberdeen Univ. Coll.; Eric B. Brooke, St. Bart.'s; Ellinor M. Burnett, Univ. Coll.; Eustace H. Cluver, Oxford and Johannesburg; Eric A. Coldrey, St. Bart.'s; Anant Y. Dabholkar, Grant Medical Coll. and Roy. Inst. Public Health; Arthur A. Denham, Edinburgh, Cambridge, and Roy. Inst. Public Health; Evelyn B. G. Ewen, Edinburgh and Univ. Coll.; Charles Glen, Glasgow; Gertrude E. Harre and Eva M. Johnson, Univ. Coll.; Jiwanlal Kapoor, Punjab and Univ. Coll.; Margherita M. Lilley, St. Andrews and Univ. Coll.; Alfred Mitchell, King's Coll.; William E. M. Mitchell, St. Bart.'s; Robert A. Olphert, St. George's and Univ. Coll.; Ian M. Rattray, Cambridge, St. George's, and King's Coll.; George C. E. Refell, Durham and Royal Inst. Public Health; Lewis R. Shore, St. Bart.'s; Harvie K. Snell, King's Coll.; Eleanor C. E. Stone, St. Mary's and Univ. Coll.; Eileen M. Turner, Univ. Coll.; and Robert G. R. West, St. Bart.'s.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.

Tridib Nath Banerjee, Calcutta; Khorshed Sorabji Captain, Bombay; Robert P. Cormack, Edinburgh and R.A.M. Coll.; David M. de Silva, King's Coll.; William H. Dye, Middlesex; David H. C. Given, Cork; Henry P. Hacker, King's Coll.; Robert J. Harley-Mason, Middlesex; David Hynd, Glasgow; Honoria S. Keer, Glasgow; Ram Nath Khosla, Punjab; Graham Louw, Edinburgh; Una F. M. Morton, Univ. Coll.; Samuel L. Navaratnam, Des Raj Nayar, Punjab; Joseph A. O'Flynn, Cork; Henry C. E. Quin, Edinburgh and Univ. Coll.; Charles F. Shelton, St. Thos. Hosp.; Prem Nath Suri, Punjab; Ernest W. Wade, Bristol and R.A.M. Coll.; and Henry O. Watkins-Pitchford, St. Thos. Hosp. (With one exception, all the above were students at the London School of Tropical Medicine.)

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

Albert H. G. Burton, Guy's, Maudsley, and Goodmayes; Charles H. Comerford, Dublin and Cane Hill; Ernest H. Connell, Edinburgh and Morningside; Gerald W. T. H. Fleming, Durham, Char. Cross, and Sunderland; Francis McLagan, St. Andrews, Maida Vale, and Hanwell; William G. Masfield, Middlesex and Severalls; George Somerville, Edinburgh and Goodmayes; and Maurice L. Sutcliffe, Univ. Coll. and Horton.

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.

Abbey Wiesener F. and Roland G. Banks-Smith, Sydney and Roy. Lond. Ophth. Hosp.; Bertram R. Bickford, Charing Cross and Roy. Lond. Ophth. Hosp.; William S. Burr, Edinburgh and Roy. Lond. Ophth. Hosp.; Thomas D. Gordon, Dublin and Roy. Lond. Ophth. Hosp.; Evan N. Hughes, Liverpool and Birmingham and Midland Counties Eye Hosp.; Kharsedji Hormusji Kamakaka, Bombay and Roy. Lond. Ophth. Hosp.; Allan P. McLeod, Sydney and Roy. Westminster Ophth. Hosp.; and Ardeshir Dadabhoi Shroff, Bombay and Roy. Lond. Ophth. Hosp.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.

Norman S. Carruthers, Guy's and Golden Square; Bernard Friedman, Edinburgh and Central London; Frank B. Gilhespy, Univ. and Birmingham and Midland Ear and Throat Hosp.; William G. R. Hore, Guy's and Central London; Geoffrey W. Robinson, King's Coll. Hosp.; and David A. Thomson, Glasgow.

The resignation of Dr. Drysdale as a member of the Council was received and accepted.—Councillors to take the place of Drs. Goodall, Hutchison, Whitfield, and Sir Charles Sherrington, retiring by rotation, and of Dr. Drysdale, resigned, were elected, on the nomination of the Council, as follows: Dr. Phear, Sir StClair Thomson, Dr. Bedford Pierce, and Sir Leonard Rogers; and, to take the place of Dr. Drysdale (for two years), Sir Walter Morley Fletcher.—Sir Francis Champneys was appointed, on the nomination of the Council, a representative of the College on the Central Midwives' Board.—Sir George Newman was elected a

representative of the College on the Executive Committee of the Imperial Cancer Research Fund, vice Dr. Sidney Martin, deceased.

The President announced that he had appointed Prof. Edwin Bramwell to deliver the Bradshaw Lecture this year, and that the Council had appointed Prof. Topley, M.D., F.R.C.P., to deliver the Milroy Lectures next year.

Admission of Women to the Fellowship.—It was resolved that the existing by-law No. 194 be repealed, and the following by-law be substituted for it:—

A woman shall be eligible for admission as a Licentiate or Member of the College and for the grant of Diplomas in special subjects on the same terms and conditions as a man, and a woman shall also be eligible for election as a Fellow of the College and shall be entitled to take part in the government, management, and proceedings of the College and to hold any office in like manner as a man is eligible and entitled.

So far as may be necessary to give effect to this By-law (a) words in the By-laws and Regulations importing the masculine gender shall be deemed to import the feminine gender also, and (b) such alterations as are requisite shall be made in the Letters Testimonial, the Form of Licence and attached Certificate, and the Form of Diploma granted by the College.

Sir Wilmot Herringham and Dr. John Fawcett were appointed as the representatives of the College to give evidence before the Departmental Committee on the University of London.

A report from Sir John Broadbent on the celebrations recently held at the University of Leeds was received, and the thanks of the College were accorded to him.—A report was received from the representative of the College on the General Medical Council on the proceedings of the Council in the session held in November last.—The College voted a contribution of 20 guineas to the St. Paul's Cathedral Fund.—Reports from the Committee of Management were received and adopted, recommending a revision of the syllabus of the examination for the Diploma in Laryngology and Otology, and in Part II. of the examination for the Diploma in Public Health.

Books and other donations to the library, presented during the last quarter, were received; also, from Mr. C. H. Golding-Bird, a miniature bust of Dr. Golding-Bird, F.R.C.P., and a portrait of Dr. Brinton from his son; and thanks were returned to the donors.

After some further College business the President dissolved the Comitia.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH,

ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The following candidates have passed the Triple Qualification Examination:—

FINAL EXAMINATION.

Joseph E. Israel, William A. D. Oliver, Vethavanam Vaithalingham, Petrus J. Badenhorst, Ebenezer A. M. McKinney, Florence M. Smith, Hee S. Foo, George E. M. Scott, Kathleen M. R. Dunn, Nathan Finn, Kulaverasingham Somaskander, Kizhakkekallattil K. Nayar, Nashid T. Yusif, Harry Krafchik, Ernest G. Douglas, James M. Rutherford, Abraham M. Filer, Rajaratnam W. Crossette-Thambiah, Norman Wren, Percy A. M. Jayewardene, John C. Shiach, Isaac Michaelson, Henry A. Newton, Arcot Vasudev, Mollie F. Churcher, Vakulabharanam V. Narasinh, Eleanor P. Topping, John T. Smith, and William M. B. Rossie.

Medicine.—Fraser D. Muller, Soo Woon Tay, William A. Kemp, Robert T. Johnson, Arumugam Chellappa, Sundaramier Ramakrishnan, Netiamvettill Karunakara Menon, James Houston, Arthur A. F. Shepherd, John Paterson, John S. Whiteside, Alexander B. Jayasuriya, John A. Hyde, Matthew L. Hendrie, Mohammed Mustafa El-Makkawi, Mohammad Junaid Quraishi, and George F. Maher.

Surgery.—Harold B. Wainer, Andrew Wilson, Fraser D. Muller, Albert E. Williamson, Moses Kopelowitz, Robert T. Johnson, Sayed Chaleb, Sundaramier Ramakrishnan, John Harkness, Arthur A. F. Shepherd, Bailey G. V. Dias, John S. Whiteside, Lim Kye Htoo, Myles E. T. Burke, Mohammed Mustafa El-Makkawi, Henry Goldsmith, James C. Stenhouse, and Mohammad Junaid Quraishi.

Midwifery.—John R. Hetherington, Harold B. Wainer, David D. H. Craig, Soo Woon Tay, Jeremiah Sabaratnam, Amarasingham, Charles K. Dowson, Netiamvettill Karunakara Menon, Donald L. Crawford, James Houston, John Harkness, Alexander B. Jayasuriya, John A. Hyde, Lim Kye Htoo, Cassaly Ismail, Matthew L. Hendrie, Henry Goldsmith, and Archibald C. Young.

Medical Jurisprudence.—Hapuarachige Don J. Lazarus, Richard A. B. Leakey, Barend J. F. Laubscher, David Lumsden, Cecil A. S. Hamilton, Moss M. Bronstein, William E. Williams, Elizabeth C. Mudie, Robert T. Johnson, Bartlet S. Ellis, Nicandro Valerio, Alexander S. Pool, Alexander Rankin, John A. Mains, Souren Kumar Mitra, Cheng Leng Tan, William Jackson, and Walter C. Heslop.

ROYAL INSTITUTION.—On Tuesday, Feb. 10th, at 5.15 p.m., Prof. J. Barcroft, F.R.S., begins a course of four lectures at the Royal Institution, 21, Albemarle-street, London, W., on the Colour of the Animal Creation. The Friday evening discourse on Feb. 20th will be given by Prof. T. H. Pear on Acquiring Muscular Skill.

ROYAL MEDICAL BENEVOLENT FUND GUILD.—The second annual concert in aid of the Guild will be held at the Wigmore Hall, Wigmore-street, London, W., on Feb. 24th, at 8.15 P.M., by the Stock Exchange Male Voice Choir, assisted by Miss Phyllis Lett and Mr. Edward Halland. Miss Harriet Cohen will play. The entire proceeds will be handed over to the Guild. Tickets from 10s. 6d. to 2s. 6d. (unreserved) may be obtained from the box office, Wigmore Hall.

LEAGUE OF NATIONS.—Among the various activities of the Health Organisation of the League during this month may be noted the Singapore Conference, which opened on Feb. 4th, and to which were invited representatives of all the Far Eastern health administrations, in order that the working details of the Bureau for Far Eastern Epidemiological Information, to be established in Singapore, might be settled. Further, an interchange of health personnel will be held in England, in which the health officials of a dozen countries, including Germany, the United States, and Russia, will take part.

NOTIFICATION OF DISEASES UNDER THE FACTORY ACT.—An Order dated Dec. 31st, 1924, has been issued by the Secretary of State extending the provisions of Section 73 of the Factories and Workshops Act of 1901, which deals with the notification of certain diseases. Under this Order, which came into effect on Feb. 1st, 1925, the following diseases, occurring in a factory or workshop, must be notified: (1) Poisoning by carbon bisulphide; (2) aniline poisoning; and (3) chronic benzene poisoning. The Order is cited as the Factory and Workshop (Notification of Diseases) Order, 1924, and may be obtained at H.M. Stationery Office, price 1d.

MEDICO-PSYCHOLOGICAL ASSOCIATION.—The next quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland will take place on Thursday, Feb. 19th, at 2.30 P.M., at the Royal College of Physicians, Queen-street, Edinburgh, under the presidency of Dr. M. J. Nolan. Dr. David Sligh will give a demonstration of the Psycho-Galvanic Reaction; Dr. George Gibson, Deputy Commissioner, General Board of Control for Scotland, will read a short paper on the Boarding-Out System; and Dr. William M. McAlister will read a short paper on Results of Treatment of General Paralysis by Malaria.

BOYLSTON MEDICAL PRIZES OF HARVARD MEDICAL SCHOOL, U.S.A.—The Boylston medical prizes, which are open to public competition, are offered for the best dissertation on questions in medical science proposed by the Boylston Medical Committee. The committee is appointed by the President and Fellows of Harvard College. A prize of \$500 and the Boylston prize medal is offered every three years for the best dissertation on the results of original research in medicine, science, or the chemical field, the subject to be chosen by the writer, and the next award will be in 1926. Dissertations must be submitted on or before Dec. 31st, 1925. The address of the secretary of the Boylston Medical Committee is Dr. Henry A. Christian, Peter Bent Brigham Hospital, Boston, Mass., from whom further particulars may be obtained.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The fifteenth meeting of the Commission was held at the Home Office, Whitehall, on Jan. 29th, Sir Andrew Duncan in the chair during the earlier part of the sitting and Lord Lawrence of Kingsgate later. Evidence was first received from Mr. J. P. Lewis, C.A., Secretary of the Hearts of Oak Benefit Society, on certain points of policy relating to investment of society funds. The main part of the sitting was devoted to the examination of Mr. Alban Gordon, who submitted far-reaching proposals for the reconstruction of the approved society system on a territorial basis and the transfer of medical and allied benefits to a unified local health service embracing all aspects of medical work. Proof copies of oral evidence and the relative statements submitted at the meeting of Jan. 15th are now on sale at H.M. Stationery Office (2s. 3d.).

ELLA SACHS PLOTZ FOUNDATION.—The Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation was established in 1923 at Boston, Mass., U.S.A., and during the first year of its existence the trustees have received 32 applications for assistance from investigators in the United States, Europe, and Australia. In eight instances grants were made of sums varying from \$500 to \$1250. Six grants were made to American workers, and of the remaining two one was to Dr. A. Besredka, of Paris, and the other to Dr. J. Abelin, of Berne. In their first statement regarding the purposes for which the fund would be used the trustees expressed themselves as follows. The object of the Foundation is to promote researches

that are directed towards the solution of problems in medicine and surgery or in branches of science bearing on medicine and surgery. As a rule preference is given to researches on a single problem or on closely allied problems. Grants may be used for the purchase of apparatus and supplies that are needed for special investigations. Stipends for the support of investigators will be granted only under exceptional circumstances. Applications should be sent to the secretary of the Executive Committee, Dr. Francis W. Peabody, Boston City Hospital, Boston, Mass., U.S.A.; applications for grants to be held during the year 1925-26 before May 15th, but if all the funds are not assigned in the spring, further consideration will be given to applications received before Sept. 15th. Applications should include statements as to the character of the proposed research, the amount of money requested, and the objects for which the money is to be expended.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—A meeting will be held at the Elizabeth Garrett Anderson Hospital on Feb. 10th, at 8.15 P.M., when a paper will be read on the Prevention of Puerperal Morbidity and Mortality: An Experimental Study in Clinical Obstetrics, by Miss Frances Ivens; Dr. V. Russell and Dr. Edith Phelps will also speak.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The fourth of the spring series of post-graduate lectures, arranged by the Fellowship of Medicine, will be delivered in the Barnes Hall at the Royal Society of Medicine, at 5.30 P.M., on Wednesday, Feb. 11th, by Dr. Andrew Balfour, who will show a cinematograph film on Malaria, with special reference to the Malaria Parasite as a Therapeutic Agent. This demonstration is open to all members of the profession, and no fee is charged for attendance.—In March courses will be held in Diseases of the Chest at the Brompton Hospital; Medicine, Surgery, and Gynaecology at the Royal Waterloo Hospital; Infectious Fevers at the North-Eastern Fever Hospital (Tottenham); Gynaecology at the Chelsea Hospital for Women; and an intensive course in General Medicine, Surgery, and the Special Departments at the Royal Northern Hospital, with which is associated the Royal Chest Hospital. Copies of the syllabus, together with the Fellowship Bulletin, may be had on application to the Secretary, at 1, Wimpole-street, London, W.

Appointments.

BAILEY, H., F.R.C.S. Eng., has been appointed Assistant Surgeon, Liverpool Royal Infirmary.
GOODWIN, A., M.D. Lond., F.R.C.S. Eng. and Edin., Surgeon to Out-patients, Chelsea Hospital for Women.
LACK, V. J., F.R.C.S. Edin., Lecturer in Midwifery and Diseases of Women, University of Birmingham
Manchester Royal Infirmary: PARKER, R. W., M.B., Ch.B. Vict., WILSON, S. P., M.Sc., M.B., Ch.B. Vict., ECCLESTON, C., M.B., Ch.B. Vict., SOMERFORD, A. R., M.B., Ch.B. Vict., WALKER, C. L., M.B., Ch.B. Vict., House Physicians; DRINKWATER, S. W., M.B., Ch.B. Vict., MACGILL, A. H., M.B., Ch.B. Vict., HEYWORTH, A. H., M.B., Ch.B. Vict., CLEGG, S. F., M.B., Ch.B. Vict., BROWN, C. V., M.B., Ch.B. Vict., House Surgeons; HUNTER W. E., M.R.C.S., L.R.C.P., House Surgeon, Specials Department; ROBERTS, W. M., M.B., Ch.B. Vict., Junior Pathological Registrar.

Vacancies.

For further information refer to the advertisement columns.
Aberdeen University.—Second Asst. in Pathology. £250.
Bath, Royal United Hospital.—Hon. S.
Bethnal Green Children's Homes, Leytonstone.—Dental Surg. £2 2s. per session.
Bethnal Green Hospital.—Dental Surg.
Birmingham and Midland Eye Hospital.—H.S. £110.
Bolingbroke Hospital, Wandsworth Common, S.W.—Res. M.O. (male) £200. Also H.S. (male) at rate of £120.
Bristol, Cossham Memorial Hospital, Kingswood.—Res. M.O. £150.
Cardiff City Mental Hospital, Whitchurch, near Cardiff.—Res. Clin. Asst. 50 guineas for six months.
Cardiff Union.—M.O. £568.
Carlisle, Cumberland Infirmary.—Res. M.O. £165 as H.P. and £185 as H.S. Also Jun. H.S. at rate of £145.
Chelsea Hospital for Women, Arthur-street, S.W.—Reg. £50.
Chesterfield and North Derbyshire Royal Hospital.—Cas. and Orthop. H.S. at rate of £150.
Colchester, Essex County Hospital.—H.S. £200. Also Asst. H.S. and Registrar. £150.
Coventry City.—Temp. Asst. M.O.H. £60 per month.
Dewsbury County Borough.—Asst. Sch. M.O. and Asst. M.O.H. £600.
Dorset Mental Hospital, Herrison, near Dorchester.—Third Asst. M.O. £300.

Dublin, Dr. Steevens' Hospital.—Hon. Obstet. P. and Gynaecologist.
 Exeter, Royal Devon and Exeter Hospital.—Sen. H.S. £250.
 Finchley Urban District.—M.O.H. and Sch. M.O. £900.
 Hastings, Royal East Sussex Hospital.—Hon. Radiologist.
 Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.
 Lanark County.—M.O.H. £1300.
 Leeds University, Dept. of Pathology and Bacteriology.—Lecturer in Bacteriology. £500.
 Leicester, City Mental Hospital, Humberstone.—Second Asst. M.O. and Pathologist. £700.
 Leicester, Isolation Hospital and Sanatorium, Groby-road.—Res. M.O. £350.
 Leicester Royal Infirmary.—H.P. £150.
 Lincoln City and County Borough.—M.O.H. £900.
 Madras and Southern Mahratta Railway Co., Ltd.—Dist. M.O. Rs.1550 per mensem.
 Maidstone, Kent County Ophthalmic Hospital.—H.S. £300.
 Manchester, Monsall Hospital for Infectious Diseases.—First Asst. M.O. £600. Also Jun. Med. Asst. £350.
 Manchester, St. Mary's Hospitals.—Res. Obstet. O. and Res. Surg. O. Each £200.
 Ministry of Pensions, Birmingham, Highbury Hospital.—Jun. M.O. £350.
 Nottingham General Hospital.—Pathologist. £350 and private fees allowed.
 Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—H.S. at rate of £100.
 Royal Chest Hospital, City-road, E.C.—Phys. Also M.O. in charge of Tuberculosis Dispensary. £750.
 Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.
 Royal London Ophthalmic Hospital, City-road, E.C.—Sen. H.S. £150.
 Royal Northern Hospital, Holloway, N.—Res. M.O. £200. Also Asst. Surg. O. £150.
 St. Mary's Hospital, W.—Second Asst. Pathologist. £250.
 Salisbury, General Infirmary.—H.S. £150.
 Weir Hospital, Grove-road, Balham, S.W.—Sen. Res. M.O. £150.
 West End Hospital for Nervous Diseases.—Asst. S., P. for Skin Dept., H.P. for In-patients. £150. Also Clin. Asst. in Speech Dept.
 West Ham County Borough.—Asst. Sch. M.O.'s. £600.
 West London Hospital, Hammersmith-road, W.—Hon. Surg. Reg. £100.
 Worcester General Infirmary.—Sen. Res. M.O. £180.
 York City Council.—M.O.H. and Sch. M.O. £1000.
 The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Penmachno, Carnarvon; Forfar, Forfar; and Bognor, Sussex.
 The Secretary of State for the Home Department gives notice of a vacancy for an additional Medical Referee under the Workmen's Compensation Act for the Bishop's Waltham, Petersfield, and Portsmouth County Courts. Applications, preferably from medical practitioners resident in Portsmouth, should reach the Private Secretary, Home Office, S.W., not later than Feb. 21st.

Births, Marriages, and Deaths.

BIRTHS.

CORMACK.—At "Elmstead," Felpham, in Sussex, on Dec. 13th, to Major and Mrs. Cormack (I.M.S.), a son.
 HUGHES.—On Jan. 30th, at Heylands, Chagford, Devon, the wife of Dr. H. L. Glyn Hughes, of a daughter.

MARRIAGES.

BRAITHWAITE—SHIPTON.—On Jan. 27th, at Littleham, Devon, John Braithwaite, M.D., D.S.O., to Margaret Shipton, of Isca House, Exmouth.
 DUFF MILLER—WALLACE.—On Jan. 29th, W. Duff Miller, M.B., Ch.B., Flight-Lieut., R.A.F.M.S. Reserve, to Muriel, only daughter of the late A. K. Wallace, Esq., and Mrs. Wallace, of Broadstone, Dorset.
 HORDER—GIVEN.—On Jan. 28th, at Mossley Hill Parish Church, Liverpool, Cecil Arthur Horder, M.B., F.R.C.S., to Jessie Given, daughter of Dr. and Mrs. Given, of Liverpool.

DEATHS.

BLACKLER.—On Jan. 31st, Henry John Blackler, M.B., D.P.H., of Reigate-hill, Reigate, aged 62.
 KNOX.—On Jan. 30th, at Strathray-gardens, Eton-avenue, N.W., Dr. Hugh Knox.
 MACCALL.—On Jan. 29th, at Wilbury-road, Hove, Sussex, William Maccall, M.D.
 ROWS.—On Jan. 28th, at Prestwich, suddenly, after an attack of phlebitis, R. G. Rows, M.D.
 N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, Piccadilly, W.
 THURSDAY, Feb. 12th.—4.30 P.M. Papers to be read: H. Muir Evans: A Contribution to the Anatomy and Physiology of the Air Bladder and Weberian Ossicles in Cyprinidae. (Communicated by Sir Arthur Keith, F.R.S.) J. S. Huxley: Studies on Amphibian Metamorphosis, II. (Communicated by Prof. E. S. Goodrich, F.R.S.)

Papers to be read in title only: Prof. A. Dendy, F.R.S.: On an Orthogenetic Series of Growth Forms in Certain Tetraxonid Sponge-Spicules. Dr. C. E. Walker: The Melotic Phase in Triton (*Molge vulgaris*). (Communicated by Prof. J. B. Farmer, F.R.S.) W. E. Alkins: *Clausilia bidentata* (Ström) and *C. cravenensis* (Taylor): A Statistical Inquiry into the Relationship of Two Similar Species. (Communicated by Prof. A. E. Boycott, F.R.S.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Feb. 9th.

WAR: at 5 P.M.

Paper:

Major A. T. Frost, R.A.M.C.: A Further Report on the Treatment of Gonorrhœa by Kataphoresis.

EPIDEMIOLOGY

COMPARATIVE MEDICINE } Special Discussion at 8 P.M.:
 DISEASE IN CHILDREN } The Control of Tuberculosis and the Milk-supply.

Speakers: Dr. Robertson (M.O.H. Birmingham), Dr. Niven (late M.O.H. Manchester), Lieut.-Colonel J. W. Brittlebank, Prof. S. L. Cummins, Mr. G. P. Male, Dr. M. J. Rowlands, Dr. Stenhouse Williams, and others.

Tuesday, Feb. 10th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.

Laboratory Meeting at the National Institute for Medical Research, Hampstead, N.W. (by invitation of Dr. H. H. Dale).

Demonstrations:

Dr. J. W. Trevan: A New Method of Studying Local

Anæsthetic Action.

Dr. J. H. Barn and Dr. H. H. Dale: A Perfusion Apparatus for Isolated Organs.

Communication:

Dr. Hermann Knaus: The Action of Drugs on Conduction in the Uterus.

Discussion on

The Action of Histamine.

Speakers:

Dr. H. H. Dale, Prof. R. J. S. McDowall.

PSYCHIATRY: at 4.30 P.M.

Clinical Meeting at the Maudsley Hospital, Denmark Hill, S.E.

Tea will be provided at 4 P.M.

Wednesday, Feb. 11th.

SURGERY: SUBSECTION OF PROCTOLOGY: at 5.30 P.M.

Discussion on

Fistula, to be opened by the President, Mr. F. Swinford Edwards.

The following will also speak: Mr. J. P. Lockhart-Mummery, Sir Charles Gordon-Watson, Mr. H. Graeme Anderson, and others.

Thursday, Feb. 12th.

NEUROLOGY: at 8.30 P.M.

Discussion on

The Etiology and Treatment of Subacute Combined Degeneration of the Spinal Cord, to be opened by Dr. A. F. Hurst and Dr. H. J. MacBride.

TROPICAL DISEASES AND PARASITOLOGY: at 5.30 P.M.

Papers:

Mr. A. F. MacCallan: Ophthalmology in Egypt.

Captain W. H. Dye, R.A.M.C.: Schistosomiasis and Splenomegaly in Nyasaland (illustrated with lantern slides and epidiascope).

OPHTHALMOLOGY:

Members of this Section are especially invited to attend the above Meeting.

Friday, Feb. 13th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)

Five Cases of Pituitary Disease will be shown by Sir Percy Bassett-Smith, Dr. Douglas Firth, and Dr. George Riddoch.

Dr. Parkes Weber will show a Case of Developmental Deformity of the Right Forearm similar to that sometimes met with in cases of multiple exostoses (diaphyseal aclasis).

OPHTHALMOLOGY: at 8.30 p.m. (Cases at 8 p.m.)**Cases:**

- Mr. Lindsay Rea: Cases of Recovery from Pseudo-Tumour of the Orbit.
 Mr. H. Neame: Case of Optic Nerve Tumour.
 Mr. F. A. Williamson-Noble: Case of Optic Nerve Tumour.
 Mr. R. S. Scott: Case of Optic Nerve Tumour.

Discussion on

The Aetiology of Miners' Nystagmus.

Speakers:

- Dr. T. L. Llewellyn: General.
 Prof. J. S. Haldane: Physiological Consequences of Work in very Dim Illumination.
 Mr. H. S. Elworthy: The Quality of Illumination in Coal-mines.
 Prof. E. L. Collis: Compensation as a Factor in the Occurrence of Miners' Nystagmus.
 Mr. G. H. Pooley: The Personal Factor in the Causation of the Disease.
 Dr. F. Robson: The Effect of Mine Gases.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 9th.—8.30 p.m., Discussion on the Treatment of Lymphadenoma, to be introduced by Sir Thomas Horder, followed by Dr. Herbert French, Dr. Neville S. Finzi, Dr. Robert Knox, and others.

BIOCHEMICAL SOCIETY.

MONDAY, Feb. 9th.—5 p.m. (Meeting in Biochemical Department, University College, W.C.).—*Communications:* H. J. Channon: Cholesterol Synthesis in the Animal Body. G. A. Harrison and H. J. Channon: Observations on the Composition of Subcutaneous Fat in Cases of Sclerema Neonatorum. C. R. Harrington: 3:4:5 Tri-iodophenyl-pyrrolidone-carboxylic Acid. J. C. Drummond and K. H. Coward: Further Observations on the Chemical Nature of the Vitamin Fraction of Cod-liver Oil. J. C. Drummond and K. H. Coward: Ultra-violet Radiation and Growth. S. Tsubura: Comparison of the Reducing Properties of Plain and Striated Muscle. P. Haas and T. G. Hill: An Oxygen Absorbing Mechanism in *Mercurialis perennis* and Accompanying Colour Changes. A. Wormall: The Tyrosinase-tyrosine Reaction: the Theory of Deamination. F. C. Happold and H. S. Raper: The Supposed Deaminising Action of Tyrosinase on Amino-acids. C. Rimington and H. D. Kay: The Phosphorus of Caseinogen (preliminary communication).

CHELSEA CLINICAL SOCIETY.

TUESDAY, Feb. 17th.—8.30 p.m. (in the clubrooms of St. George's Hospital). Sir Thomas Parkinson and Mr. A. R. Thompson will lead a discussion on the Diseases of the Climacteric Period in Both Sexes.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, Feb. 13th.—Dr. Harold Pritchard: Some Aspects of Modern Medicine.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.**ROYAL COLLEGE OF SURGEONS OF ENGLAND** Lincoln's Inn-fields, W.C.

MONDAY, Feb. 9th.—5 p.m., Prof. V. E. Negus: Some Disorders of the Larynx.

WEDNESDAY.—5 p.m., Prof. R. Lawford Knaggs: Osteitis Deformans and its Relation to Fibrosa and Osteomalacia.

FRIDAY.—5 p.m., Prof. Stanford Cade: Regional Anæsthesia.

SATURDAY.—4 p.m., Sir D'Arcy Power: Hunterian Oration.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

MONDAY, Feb. 9th, to SATURDAY, Feb. 14th.—WEST LECTURE HALL, Royal Society of Medicine, 1, Wimpole-street, W. Demonstration arranged by the Fellowship of Medicine, and open to all members of the medical profession. Wednesday, Feb. 11th, 5.30 p.m., Dr. Andrew Balfour will show a Film on Malaria, with special reference to the Malaria Parasite as a Therapeutic Agent.—COMBINED COURSE IN DISEASES OF CHILDREN, Paddington Green, Victoria Hospital, and Children's Clinic. Two sessions daily as per syllabus.—LONDON LOCK HOSPITAL, 91, Dean-street, W. Comprehensive Course. Clinical work daily and lectures.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, Leicester-square, W.C. Demonstrations daily in the various departments. Pathological demonstrations arranged for and Tuesday and Thursday special lectures. Tickets for this particular course from the Fellowship.—LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, N.W. Tuesday and Thursday, 2 p.m. Clinical Demonstration by Dr. G. C. Low and Dr. Manson-Bahr.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

TUESDAY, Feb. 10th.—4.30 p.m., Dr. J. Browning Alexander: Treatment of Pulmonary Tuberculosis, with special reference to Artificial Pneumothorax.

FRIDAY.—4.30 p.m., Dr. S. Cochrane Shanks: Electro-diagnosis.

Daily: In-patient and Out-patient Clinics in General and Special Departments, Operations, &c.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Feb. 10th.—5 p.m., Dr. W. Griffith: Eczema.

THURSDAY.—5 p.m., Dr. W. Griffith: Eczema.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL POST-GRADUATE LECTURES, Marylebone-road, N.W.

THURSDAY, Feb. 12th.—5 p.m., Mr. A. W. Bourne: Treatment of Placenta Previa.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, Feb. 9th.—12 noon, Mr. Shummonds: Applied Anatomy. 2 p.m., Mr. Addison: Surgical Wards. 2 p.m., Dr. Scott Pichin: Medical Out-patients.

TUESDAY.—11 a.m., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2 p.m., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—12.15 p.m., Dr. Burnford: Medical Pathology. 2 p.m., Dr. Owen: Medical Out-patients. 2 p.m., Dr. Dowling: Skin Dept.

THURSDAY.—11 a.m., Sir Henry Simpson: Gynaecological Wards. 2 p.m., Mr. MacDonald: Genito-Urinary Dept. 2 p.m., Mr. Bishop Harman: Eye Dept.

FRIDAY.—11 a.m., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 p.m., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 a.m., Dr. Burnford: Bacterial Therapy. 10 a.m., Dr. Saunders: Medical Diseases of Children. 10 a.m., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 a.m. to 6 p.m., Saturdays, 10 a.m. to 1 p.m., In-patients, Out-patients, Operations, Special Departments.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.**POST-GRADUATE COURSE:** FEB.—MARCH, 1925.**CLINICAL LECTURES AND DEMONSTRATIONS.**

MONDAY, Feb. 9th.—2 p.m., Out-patient Clinic: Dr. Hinds Howell. 3.30 p.m., General Treatment of Paraplegia: Dr. Riddoch.

TUESDAY, Feb. 10th.—2 p.m., Out-patient Clinic: Dr. Adie. 3.30 p.m., Compression Paraplegia due to Tumours: Mr. Armour.

THURSDAY, Feb. 12th.—2 p.m., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 p.m., The Diagnostic Significance of Tremors: Dr. Risien Russell.

FRIDAY, Feb. 13th.—2 p.m., Out-patient Clinic: Dr. Gordon Holmes. 3.30 p.m., Some Forms of Acute Encephalitis: Dr. James Collier.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.

THURSDAY, Feb. 12th.—12 noon, The Cerebro-spinal Fluid, Physiology and Pathology: Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

MONDAY, Feb. 9th.—12 noon, Afferent Paths and Physiology of Sensation: Dr. Hinds Howell.

The Fee for this Course will be £2 2s.

Dr. H. J. Macbride will give a COURSE OF EIGHT CLINICAL DEMONSTRATIONS, chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM, in the Wards at 10 a.m. on Tuesdays and Fridays, if sufficient entries are received. The Fee for this Course will be £2 2s.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.

WEDNESDAY, Feb. 11th.—3.30 p.m., The Optic Nerve: Mr. Leslie Paton.

Applications for this Course should be made early. Fee £5 5s. if taken as a separate Course, or £3 3s. if taken with the General Course.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 a.m., or at such other times as may be announced.

Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course. J. G. GREENFIELD, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 12th.—4 p.m., Mr. Barrington-Ward: Hernia.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE (at Whitworth-street West Branch).

FRIDAY, Feb. 13th.—4.30 p.m., Mr. Morley: The Indications for Operation in Tuberculous Adenitis.

ANCOATS HOSPITAL, MANCHESTER.

THURSDAY, Feb. 12th.—4.30 p.m., Mr. Diggle: Diseases of the Oesophagus.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 p.m.)

MONDAY, Feb. 9th.—(At the Children's Hospital.) Mr. Thompson: Congenital Pyloric Stenosis.

TUESDAY.—(At the Southern Hospital.) Mr. Nuttall: Surgical Cases.

WEDNESDAY.—(At the Northern Hospital.) Dr. Leith Murray: Sterility.

THURSDAY.—(At the Stanley Hospital.) Dr. Oram: Radiology of Fractures.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

TUESDAY, Feb. 10th.—4 p.m., Dr. Bryson and Dr. Orr: Review of Cases Illustrating the Relation of Cardio-vascular Disease to the Kidney. Discussion.

THE PEOPLE'S LEAGUE OF HEALTH.

Lectures on What We Should Eat and Why, at the Medical Society of London, 11, Chandos-street, W.

WEDNESDAY, Feb. 11th.—6 p.m., Prof. R. H. A. Plimmer: Diseases Caused by Badly Chosen Diets.

THE INSTITUTION OF HEATING AND VENTILATING ENGINEERS, Victoria-street, S.W.

WEDNESDAY, Feb. 11th.—2.30 p.m. (At the Old Colony Club, Aldwych House, W.C.) Mr. A. H. Barker, B.Sc. (Past President): Unsettled Questions in Heating and Ventilation.

Notes, Comments, and Abstracts.

FOLK MEDICINE.*

BY WILLIAM MURPHY, M.B., CH.B. LEEDS.

FOLK medicine belongs neither to any one period of time nor to any particular race. It arose with the dawn of man's intelligence. It seems likely that it is far older than even the incredibly ancient mythic traditions of the great primitive races, just as it has persisted long after they have passed into oblivion. Folk medicine belongs rather to a stage in mental evolution than to any period in time, and that many of us have not yet passed beyond that stage we have frequent and convincing proof. We still find people who rub styes with wedding-rings, who carry potatoes as a charm against rheumatism, who spit on warts—and even some who believe that Kruschen salts will rekindle the fires of their lost youth. What some of us may be less ready to admit is the connexion between recognised medicine and the crude and superstitious remedies of the witch or the ignorant housewife. The Edinburgh Pharmacopoeia of 1737, which, we are told, was in request all over Europe, and which aimed at a reformation of pharmacy, yet contained such choice ingredients as the juice of woodlice, dried toads, powdered skulls, human fat and urine. The last has apparently not yet disappeared from the pharmacopoeia of superstition. I know of a doctor who, having asked a patient for a specimen of urine, only obtained it after pledging his word that he would not put it in the medicine. After studying a "Materia Medica" so comprehensive as this, one feels that imagination has indeed failed modern pharmacologists. There is, however, one ancient superstition, formerly current in the profession, which cannot be said to have disappeared from it. Chaucer's doctor, we are told, loved "gold in especial" because it was a "cordial in physic." In spite of the growth of scientific knowledge, this strange affection has persisted in our midst, and I doubt not that the reason for it is not very different from that at which Chaucer was slyly hinting.

Essentially, however, folk medicine, though it may from time to time have coloured the teachings and practice of the learned, belongs to the folk themselves, and since it is so intimately bound up with the history of human progress, it must of necessity have some interest to those in any way concerned with the development of human mentality and the relief of human suffering. Folk medicine grew out of man's daily needs and fears and beliefs. It was the outcome of his observation of the great primal facts of existence—birth, suffering, death. It was intimately associated with every aspect of primitive existence. It was part of primitive religion. Originally the doctor and the priest were one—a combination of functions which would nowadays, perhaps, cause many members of the profession some embarrassment.

The Mystery of Death.

To primitive man we may well believe that death was an insoluble mystery. Intellectual man has not yet discovered a wholly satisfactory explanation of death—or of life, although science has formulated and discarded many theories on the subject. The great French philosopher, Descartes (seventeenth century), actually believed that the pituitary gland was the bond between body and soul. One step forward, however, we have made. We have learned to regard death as a natural event. Primitive man—if we may draw conclusions from the beliefs of savage tribes still in existence—was quite unable to visualise it as a natural occurrence at all, possibly because in his experience it was so frequently associated with violence. He connected death with wild beasts, drowning, lightning, or—and this much more rarely—with mysterious affections of his body which he could not understand or account for. So he came to attribute death and all physical suffering to supernatural causes, of which there would seem to have been three of paramount importance: (1) The anger of offended spirits, (2) the supernatural power of an enemy, (3) the displeasure of the dead.

Spirits to our unsophisticated forefathers were an ever-present source of trouble, and disease was long regarded as a mark of the wrath of those powerful beings. Among certain Asiatic tribes a favourite treatment for disease of any kind was for the village sorcerer to thrash the patient until the demon was driven out of him. In Burmah, if thrashing proved ineffectual, the doctor was wont to trample on his patient's abdomen until he killed the demon.

In England the Devil was long credited with the power of inflicting disease and also, if he felt so inclined, of curing it. He seems indeed to have been held in some respect as the head of the medical profession—a view which doubtless still

claims some adherents! Sir George Mackenzie, writing in the seventeenth century, states that "the Devil can cure disease because he knows its natural causes better than the physicians can, who are not present when diseases are contracted and who, being younger than he, must have less experience."

The power of enemies was scarcely less dreaded than the wrath of spirits. A curse was a potent cause of death or misfortune, though most commonly the desired effect was only obtained by the mediation of some person skilled in the practice of magic. The witch—or wizard as it sometimes was, though more rarely in England—might compass the evil by means of incantations or prayers—usually addressed to the Devil—but sometimes she required for the success of her spells something intimately associated with her destined victim, like a lock of his hair or a piece of his clothing. It seems probable that the old-fashioned nurse's eagerness to commit at once to the fire such things as pieces of nails or hair arose out of nothing more hygienic than this old superstition. A method still more favoured by the witches was the burning of a waxen or wooden image of the person upon whom the spell was to work, in the belief that as the wax melted or the wood charred so the body of the victim wasted or was tormented. The "evil eye" was for centuries, and, indeed, in some places still is, an object of superstitious dread. One writer even tells us that the reason why surgeons do not show wounds to every man is that they have observed that the influence of some eyes hinders the process of healing.

The belief that the dead could cause suffering to the living probably belongs to a much later stage in the history of culture than either the fear of spirits or of witchcraft, and it has survived both of them. It is still commonly thought that if a corpse be allowed to remain in the house over a Sunday there will be two more deaths in the family. As late as 1887 the body of a woman who had died of phthisis was exhumed and her lungs burned because she was believed to be drawing the remaining members of her family into the grave after her. This story, I perhaps ought to add, comes from America, where perhaps even popular medicine may transcend common experience, as does the length of the American appendix! The belief in vampires is probably akin to this fear of the dead, a belief not yet extinct even in the civilised world. So recently as a couple of years ago a case was reported from Central Europe in which the body of a dead woman was taken from the grave and a stake driven through her heart—that having been for centuries the recognised means of dislodging the evil creature which was using the dead body to pursue its hideous work.

To say that all misfortune was attributed to one of these three great causes would, of course, be inaccurate, but they were the most potent influences for evil and the most dreaded.

Cure by Transference.

Having discovered for himself a satisfactory reason for his troubles, man naturally turned his mind to what concerned him much more nearly—namely, the curing of them. Disease, he noticed, was frequently though mysteriously conveyed from one person to another, and from this observation he deduced a simple means of ridding himself of his aches and pains. He argued that, since a witch or a spirit could inflict disease upon a man, surely that man ought in turn to be able to transfer it to some creature inferior to himself—a slave or an animal. There were innumerable methods of effecting this transference, the simplest of which was, perhaps, that in which the patient was recommended to sit on a donkey with his face to the tail and wait for his pain to be transmitted to the animal. Ague was cured by more unpleasant though possibly less tedious treatment. The patient, having been securely pegged to the trunk of an oak-tree by a lock of his hair, was bidden to free himself by a sudden wrench, the theory being that as the lock of his hair was transferred to the tree so also was the ague. The physician of James I., Sir Kenelm Digby, treated toothache by cutting the gum with an iron nail and then driving the nail, when it was satisfactorily covered with blood, into an oak beam, a treatment which he claimed to be infallible. Witches were commonly credited with the power of transferring disease—a belief not inconvenient for the medical practitioner, since any failure on his part to obtain a cure was regarded as strong evidence that his patient was bewitched.

Cure by Association.

Cure by association was another popular type of remedy, closely resembling in many cases cure by transference and not always to be distinguished from it. The vulgar direction to "take a hair of the dog that bit you" did not originally mean that you were to have another glass on the morning after, but was intended literally. Dog's hair was commonly applied in cases of dog-bite, being considered especially efficacious if you could procure the hair of the actual offender. In cases of hydrophobia dog's liver was administered to the patient. A case is on record in which a mad dog was drowned and after nine days its body was recovered in order that its liver might be given to a child whom it had infected. The

* A paper read before the Leeds University Medical Society.

chronicler naïvely adds that the child died. It was common among recognised practitioners as late as the seventeenth century to treat the weapon with which a wound was inflicted and not the wound itself—a custom probably fraught with much less danger to the patient. Boyle, in his "Usefulness of Experimental Philosophy," tells of a doctor who, suffering from some apparently incurable disease, was advised to boil an egg in his own urine and bury the egg in an anthill, in order that as it wasted his disease might abate, and—says the great scientist—he found the treatment eminently successful.

As might be expected, many folk-remedies were connected with the offering of sacrifice, though few of them have survived into modern times, possibly on account of their intimate association with pagan religion. A belief which may certainly be said to have been similarly associated, but of which traces still remain, was that in the possibility of entering life afresh by a symbolical "new birth." We still find that in certain districts mysterious powers are attributed to trees whose trunks have split in such a way that it is possible for a person to pass through them—an action which signified that the patient entered upon a new life, leaving behind him all his old pains and troubles. Croker, in his "Legends of Killarney," relates how he came across a tree of this kind and was urged by his guide not to lose the chance of squeezing through. On inquiring the reason he received the following reply: "It will ensure your honour a long life, and if only you was a lady in a certain way, there'd be no fear of you after going through!"

Superstitions and Charms.

The spread of Christianity, whilst it tended to discourage many old pagan beliefs, brought in its train new superstitions. There are still extant many old prayers and invocations which are really nothing more nor less than charms. The sign of the cross, as might be expected, plays a very important part in popular medicine. It served not only to keep away devils of every description, but it was also an infallible protection against the "evil eye." Made in saliva upon a foot which had gone to sleep, its effect was instantaneous. In certain parts of England the patient with ague makes three crosses in white chalk upon the chimney back, and as they slowly blacken with the smoke his disease is supposed to abate. Children with whooping-cough are commonly given a ride on a donkey, because of the cross on its back, supposed to have been imprinted there after the triumphal entry of Christ into Jerusalem. Hairs from the animal's back are, for the same reason, credited with miraculous power. The family doctor might care to know that, hung in a bag round a child's neck when teething, they are very efficacious as a preventive of fits!

Difficult to understand—in view of man's fear of the dead—is the faith placed in the healing properties of objects associated with death. Various parts of a dead body were believed to be possessed of healing properties. A powder made of human bones was commonly administered in cases of epilepsy, and a volatile salt extracted from human skulls was among the remedies prescribed in 1680 by the 14 physicians who attended Charles II. in his last illness—which is now believed to have been an apoplectic seizure. Much of the body-snatching of the seventeenth and eighteenth centuries is doubtless to be attributed to this superstitious belief in the virtue of the dead body. Faith was placed even in the touch of a corpse's hand, and at one time sufferers attended executions in great numbers in order to receive what was known as the "dead-stroke," the fee for the privilege being collected by the hangman!

Such details as colours and numbers were important factors in the art of healing, as practised by the ignorant. Red has always been popular in folk-medicine, and is to this day; we probably have most of us come across people who swear by red flannel as a preventive of chest troubles, and will accept material of no other colour. The following is the time-honoured method of treating a sty:—Catch a black tom-cat on the first night of the new moon, pluck a hair from the end of the tail, and it will be found that after the sty has been rubbed with the hair nine times, it will gradually disappear. Blood from the same cat's tail was supposed to have a beneficial effect when applied to shingles. While on the subject of colour, may I warn all of you that it is extremely dangerous to pass a white horse without spitting at it! Among the numbers, none is so popular as three and its multiples. If a snake be allowed to crawl nine times across a swelling in the neck the swelling will disappear. A child suffering from whooping-cough should be passed three times under and over a donkey on nine consecutive days—another cogent reason why the family doctor should invest in one of these useful animals. The cure for epilepsy was to go head-first down three flights of stairs on three successive mornings!

The Influence of the Moon.

That the moon should be regarded with superstitious awe is not surprising. Galen himself believed that the moon

controlled fits of epilepsy, and it is only comparatively recently that the association between the moon and lunacy was officially discarded by the profession. It is a persistent belief that death commonly occurs at low tide—the tides being simply a manifestation of the potent influence of the moon. The death of the immortal Falstaff will be familiar to all of you. "A parted," says the hostess of the Eastcheap Tavern, "'A parted even just between twelve and one, ev'n at turning o' the tide.'" Still better known is the description of the death of old Barkis—"He's agoing out with the tide," said Mr. Peggotty to me, behind his hand. My eyes were dim, and so were Mr. Peggotty's. 'With the tide?' 'People can't die along the coast,' said Mr. Peggotty, 'except when the tide's pretty nigh out. They can't be born unless it's pretty nigh in—not properly born till flood. He's agoing out with the tide. It's ebb at half arter three, slack water half an hour. If he lives till it turns, he'll hold his own till past the flood and go out with the next tide.'" Then a little further on we read: "I was on the point of asking him if he knew me when he tried to stretch out his arms and said to me distinctly with a pleasant smile: 'Barkis is willin'.' And, it being low water, he went out with the tide."

Apart from these somewhat general superstitions, domestic medicine, of course, recognised healing virtues in innumerable common objects and even in certain individuals. A seventh son was always believed to be possessed of remarkable power, and was from infancy a useful source of income to his parents. That marvellous cures should be performed by a twenty-eighth son born without the intervention of a daughter, is perhaps hardly surprising. Warts might be speedily removed by rubbing them against the person of the father of an illegitimate child, a treatment which we may imagine was not always devoid of excitement. Animals were credited with all kinds of powers. The head of a mad dog powdered and mixed with wine cured jaundice. A horse hair on a slice of bread-and-butter was given to children with worms in the hope that it would choke the worms. Both witches and the medical profession regarded the hare with peculiar favour. Its brain was good for over-sleeping; its lungs healed sore eyes; and the whole animal, skin and all, baked to powder was, we are told, "wonderful good for the stone."

Conclusion.

How many of these old remedies are still in use it is difficult to say, but belief in them dies hard, and we may safely conclude that in private many of them are still resorted to by the ignorant. Victor Hugo says somewhere that when you have killed ignorance, you will have destroyed crime. We may perhaps adapt that to our subject and say that when we have killed ignorance we shall have destroyed superstition. But ignorance can hardly be said to have disappeared whilst we still have in our midst the old man who, having told the doctor his old woman had a pain in her brains, and being asked where she kept her brains, clapped his hand to his abdomen and said, "Why here, Doctor, o' course, in her belly!"

HEALTH CONDITIONS IN KENYA COLONY AND PROTECTORATE.

IN the report for 1923, just issued, it is stated that no census of the non-native population has been taken since 1921, and the native population is the subject of a rough estimate only. The registration of European births is compulsory, and the relative statistics for 1923 are as follows: Births 194, or a crude rate of 20.1 per 1000; deaths 65, or a crude rate of 6.6 per 1000. The respective figures for 1922 were 27.04 and 9.04. Reliable figures of these rates amongst Asiatics and Africans cannot be given, but, taking the total population of certain towns and the total number of deaths reported, it appears that in Mombasa the crude death-rate was 16.6 per 1000 as compared with 16.7 in 1922; in Nairobi it was 23.5 as against 21. The population figures are recorded in the census report as: Europeans 9651, Indians 22,822, Goans 2431, Arabs 10,102, others 627—a total of non-native population of 45,633. The native population is estimated at 2,500,000. Though no epidemic occurred during 1923 there was a disquieting prevalence of small outbreaks of plague. None of these was severe, but it is clear that the range of this disease is spreading, and as the resources of the country are developed it may be expected that the incidence of plague will also grow. Further research work into the epidemiology of plague is necessary. Vaccine is now produced locally in the bacteriological laboratory. The incidence of pneumonia during 1923 calls for remark. The figures from five sources outside the reserves show that 1223 cases were treated, of which 385 terminated fatally, a percentage of 31.5. Included in these are the figures from the Nasin Gishu Railway, where, owing to climatic and other conditions, the incidence and mortality were higher than elsewhere.

Though many more natives applied for treatment for leprosy in 1923, it is not considered that this disease is extending, but rather that confidence in Government doctors is increasing. During the year 236 cases were reported, as compared with 81 in 1922; the bulk of this increase occurred in Chuka, Kisii, and Kakamega. Accommodation for lepers has been provided at these stations. There are also leper establishments at Malindi and Lamu, in which respectively 48 and 8 lepers are resident.

Considerable progress was made in the medical work in native reserves during the year. The total number of in-patients treated at hospitals in 1923 was 32,229, as against 37,384 in 1922, but the number of out-patients increased from 165,538 to 245,554, owing to the greater use made of the 46 sub-dispensaries in charge of African dressers, at which 110,509 patients were treated. No new central hospitals were opened in 1923, but some idea of the extent of the activities of the doctors in charge of these African hospitals is obtained by a glance at the figures of the three essentially native reserve stations, and, in order to show how the work has expanded, comparative figures for 1922 are also given:

	In-patients.		Out-patients.		Out-dispensaries and treated by medical officer on tour.	
	1922	1923	1922	1923	1922	1923
Chuka . . .	4470	3757	552	1775	—*	5,672
Kisii . . .	5624	2796	3,565	8306	—*	22,811
Kakamega . .	2179	1105	27,071	9271	—*	28,017

* Included under out-patients.

There was a great extension of the medical campaign against yaws; 64,344 cases were treated, compared with 34,233 in 1922, and this increase has been made possible by the more frequent tours of medical officers, and, in the Fort Hall district, by the stationing at the out-dispensaries of African dressers specially trained to give injections of bismuth. The expansion of this campaign was facilitated by the perfection and use of extremely inexpensive substitutes for novarsenobillon, and there has resulted a most marked and welcome change in the attitude of natives to the European doctor; whereas formerly the doctor and the hospital were feared, now natives have gained confidence from the knowledge that thousands of their fellows have been quickly cured of a widespread crippling disease. This is shown by the increased number of applicants for admission to hospital, and of those who are willing to submit to prophylactic treatment against such menaces to public health as plague and small-pox. In 1922, 18,737 persons were inoculated against plague, and 57,246 were vaccinated. In 1923 the respective figures were 122,460 and 56,345. The accommodation of the native hospitals at Mombasa, Nairobi, and Kisumu has been severely strained (the total accommodation at Nairobi is 190 cases), and during the year extensions were added—e.g., a dysentery ward at Nairobi and at Kisumu a new ward with 20 beds.

The training centre for African dressers is the Nairobi Native Hospital, where quarters for 15 learners have been provided. A beginning has also been made with the training of African dispensers. It is also the case that at the Bacteriological Laboratory six Africans were engaged in 1922, and are making good progress. A curriculum has been drawn up, and in the course of a few years (the normal training period will be three years) African assistants will, it is hoped, be ready for drafting to out-stations and be capable of performing all the more ordinary microscopical and other examinations required in the routine work of a hospital.

Attention is directed to the action taken to reduce drunkenness in native reserves by the enactment of the Sugar Ordinance Act, 1923. In certain native reserves, especially the Akamba Reserve, there has been prolific cultivation of sugar-cane. The cane was sold to millers, crushed into jagree, and re-sold to the natives, who then allowed it to ferment. Drunkenness increased to such an alarming extent that it became of vital importance to the well-being of the tribe to prohibit the manufacture of jagree. The new Ordinance prohibits the supply to a native, directly or indirectly, of sugar juice extracted by the use of any machinery designed for or capable of producing sugar juice, and the possession of a mill or other apparatus within proclaimed areas except under permit from the Government.

The rainfall in 1922 over the country as a whole was deficient, though on the coast that year was the wettest on record. In 1923 the rainfall was abundant and well-distributed—a fact exemplified no less by the abundance of crops than by the statistics of the various stations. As regards rainfall, Kenya may be divided into three parts. In the northern deserts, in Jubaland, and in the tracts of Tanaland

the rainfall is less than 20 inches a year. The coastal strip and the Nyanza and Kikuyu provinces have between 40 and 80 inches, and the remainder of the country from 20 to 40 inches of rain a year. At the coast the climate is tropical, though the temperature at Mombasa seldom rises above 87° F. in the shade. Up-country the heat is rarely intense, and in the cold season fires at night are welcome. Throughout the country the direct actinic ray compels the wearing of helmets or terai hats from 8 A.M. to 4.30 P.M.

FIRST-AID FOR THE CAR.

A LITTLE handbook entitled *First Aid for the Car* has been recently issued by Sterns, Ltd., and may be obtained free of charge on application to them at Royal London House, Finsbury-square, London, E.C.2. It measures only 4½ in. by 2½ in., but its 24 pages contain information which may be of great value to the puzzled amateur. It is arranged in tabular form under the headings symptoms, cause, and remedy for each vital system of the car. For example, under the section headed *magneto* we find various possible causes for absence of spark or misfires, with the appropriate treatment. Some of the treatment suggested is easier to read about than to carry out, even for the professional repairer, and to the ordinary owner-driver the handbook will probably be more useful as an aid to diagnosis. The two pages devoted to the motorist's own troubles should be revised or omitted. The application of arnica to bruises, the stimulation of a concussed patient, and the administration of brandy in sunstroke are not the methods that would now be advised by doctors, nor is the application of cold to the spine the best treatment for nose-bleeding.

DONATIONS AND BEQUESTS.

Alderman J. Harrison Jones, J.P., left £1000 to Liverpool University, £500 each to the Royal Infirmary, the Southern Hospital, the Bluecoat Hospital, and the Northern Hospital, Liverpool.—Glasgow University students, in a carnival on Jan. 17th in aid of local infirmaries and charities, collected over £700.—Mr. David Dunlap, of Northern Ontario, bequeathed £50,000 each to the Victoria University and the Toronto General Hospital.—During the past month the governors of the Royal Manchester Children's Hospital have received legacies and subscriptions amounting to over £2900, including legacies of £1000 from John G. Litton, £350 from the trustees of the late Mrs. Eliza Smith for X ray apparatus for the hospital, £500 from the Bleachers' Association; Booth charities, £250; Queen Alexandra Flower Carnival, £272; and the executors of the late Mrs. J. W. Burden, £100.—Mr. Frederick Ralph Norman Kendall, of Loxley, Warwick, left £1000 to Dr. Barnardo's Homes; £500 to Stratford-on-Avon Hospital; £300 to Stratford-on-Avon Nursing Home; and £200 to the Society for the Prevention of Cruelty to Children.—The Chelsea Hospital for Women has received from the trustees of the Zuntz Bequest, £600 towards the upkeep of its Annie Zuntz Floor.—Mr. John Henry Beeby, Peterborough, left £1000 to Peterborough Infirmary and Dispensary, and £500 to the National Children's Home and Orphanage.—Mrs. Margaret Booth Leach, Bournemouth, bequeathed a legacy of £500 to the Wigan Infirmary.—Sir Harold Bowden has sent a donation of £1000 to the Nottingham Cripples' Home.—Mrs. Annie Elizabeth Lee, of Thorp Arch, Yorks, left £500 each to the Leeds General Infirmary, the Leeds Women's and Children's Hospital, Cookridge Home, and similar amounts to other Leeds non-medical institutions. After fulfilment of personal bequests part of the residue will go to the Women's and Children's Hospital.—The late Colonel Sir Arthur Lever left, among other bequests, £500 to the Leicester Infirmary and £500 to the Middlesex Hospital.—By the will of the late Miss Sophia Hewitt, of Dedham, near Colchester, the testatrix left, among other bequests, £2000 to the British Home and Hospital for Incurables; £2000 to the Eastern Counties Institution for Idiots, Colchester; and £1000 each to the Association in Aid of the Deaf and Dumb, the Surgical Aid Society, and the Zenana Bible and Medical Mission.—Mr. Edward Thomas Duncombe Stokes, Woodford, Essex, left £1000 to the City of London Hospital for Diseases of the Chest, Victoria Park.—After the fulfilment of certain personal and other bequests the residue of his property, amounting to £8328, has been left by the will of the late Mr. H. C. Durham, of Bedford, to Bedford County Hospital.—Mr. George Somervell, Windermere, bequeathed £500 to the Westmorland County Hospital and a similar sum to the London Association in aid of the Moravian Missions for the Leper House at Jerusalem.—Sir Harry James Veitch, the well-known horticulturist of South Kensington and Chelsea, who left property of the value of £79,395, gave £1000 to Dr. Barnardo's Homes and a similar amount to five other societies and missions.

Recent Knowledge

OF THE SPLEEN.

*A Lecture delivered to the Manchester Medical Students' Club
on Jan. 15th, 1925.*

By JOSEPH BARCROFT, C.B.E., F.R.S.,
READER IN PHYSIOLOGY, UNIVERSITY OF CAMBRIDGE.

THE story I have to relate opens somewhere about the place where the Atlantic becomes the Caribbean Sea, and in the last days of 1921, when, on the deck of the R.M.S. *Victoria* of the Pacific Steam Navigation Company, three of the passengers might have been seen engaged in practices which were, to say the least of it, unusual among the habitués of ocean liners. For Prof. Meakins, then of Edinburgh, now of Montreal, Mr. Doggart, of King's College, Cambridge, and myself were parading the deck, our noses firmly clipped, breathing from rubber bags which we patted and shook the while. By and by we sat down and transferred the ritual of patting the bag to another, but before we ceased from inhaling the "vapour" of the bag a small sample of our blood was taken for analysis. In other words, the blood volume was being measured. The bag contained oxygen, but with it a certain measured amount of carbon monoxide. The carbon monoxide was in time practically all absorbed in the lung by the blood-stream, through which it was distributed, so that if the amount of carbon monoxide in each cubic centimetre of blood was ascertained (which can be done from the sample), and if that amount be divided into the whole quantity absorbed from the bag, the quotient gives the blood volume. So much by way of description of the method of Haldane and Lorrain Smith as we used it.

But although the story commences with our entry into the Caribbean Sea, we had made measurements on ourselves before leaving Europe, and on such rare occasions as the weather permitted of, had done the same on our voyage—we were bound for the Andes—but hitherto our determinations had been consistent; now they seemed to be going wrong in the case of each subject; apparently, the blood volume was increasing. Moreover, it was not simply the quantity of fluid that was gaining, but the hæmoglobin in circulation was mounting up also. This was a most disconcerting circumstance, because our ambition was to study the alterations in the hæmoglobin wrought by high altitudes; for this study it was necessary to obtain a sea-level base line, and now our base line was slipping from us. However disappointing it might be, there was no escape from the facts. Up went the blood volume day by day; up went the hæmoglobin, and this went on until we reached the Panama Canal, when a change took place, and the tide of hæmoglobin—so to speak—commenced to abate. By the time we reached Callao both the blood volume and the hæmoglobin in circulation were above the normal figures, but much below the Panama maximum. What was the explanation? Was it some error in our instruments or was it a real phenomenon, and if the latter were true, what was its significance?¹

INCREASE IN BLOOD VOLUME WITH INCREASED TEMPERATURE.

We had been using but one method for the analysis of the blood—it is always bad to be dependent on one method—coming back we used three. In general the results were the same, though not so clear cut. Of course, having been at all sorts of temperatures and altitudes we were in a less stable condition. Inadvertently this word has slipped out which I had reserved for emphasis—"temperatures"; for it was remarkable

enough that the curve of our blood volumes ran almost parallel to that of mean temperature of our cabins—rising as we approached the tropical heat of Central America, falling as we entered the cooler "Humboldt current" on the West Coast of South America. Were we right in supposing that temperature was the cause, not something coincident with the vascular changes which interested us? The matter was not difficult to test subsequently at home. Two colleagues, Drs. Davies and Fetter, offered themselves for the purpose. Each lived for three days in the glass room which forms part of the equipment of the Cambridge Physiological Laboratory. The season was one of snow; the temperature of the glass room was maintained at 90–95° F. day and night. The blood volume was measured independently by Dr. Davies, Prof. Meakins, and myself. The changes were just such as had taken place at sea and now clearly were due to rise in temperature. The physiological significance is clear enough; large cutaneous vascular areas are opened up in response to the heat, the blood to fill them must come from elsewhere, and as "elsewhere" may have need of it, it is desirable to have a volume of blood commensurate with the size of the vascular bed.

But I must repeat it was not merely the amount of water in circulation which was influenced by temperature—a matter with which Barbour has already dealt.² It was the total amount of hæmoglobin. The mystery was: "Whence came this outpouring of hæmoglobin?" It was not credible that the bone-marrow could have provided the body with new corpuscles at the rate required. Moreover, there was no evidence of increase of immature corpuscles in circulation on the way home from Peru, and only on the third day of the Davies and Fetter experiment—but quite definitely then—was there evidence for increase in the immature (reticular) erythrocytes.

THE BODY'S HIDDEN STORE OF HÆMOGLOBIN.

The question then was forced upon us: Has the body any considerable but hidden store of hæmoglobin which can be drawn upon in case of emergency? Note the two adjectives "considerable" and "hidden." Let me pass to the consideration of the latter. "A hidden store," in the sense I use the term, must mean a store to which carbon monoxide has no considerable access in, say, 20 minutes inhalation of quantities of the gas not too large to be readily tolerated by the central nervous system.

In searching for a locality which might fulfil such a condition one naturally seeks in the first instance for some place where the red blood corpuscles are outside the circulatory system—some backwater outside the arteries, capillaries, and veins. There is only one such place of any considerable size in the body—that place is the spleen. There the general mass of the spleen pulp is laden with erythrocytes. To what extent may these be said to be in circulation? About the time of which I speak Dr. Duncan Scott was making measurements of the volume of the blood in rats.³ His measurements were made by the carbon-monoxide method, and I have to thank him for the permission which he granted me to investigate the spleens of these animals. Although the blood in the general circulation at death contained a very high percentage of carbon monoxide, the hæmoglobin contained in the spleen pulp contained practically none. This observation was confirmatory of one made by Heger⁴ to which little attention has been paid—namely, that in some persons who died of rapid inhalation of carbon monoxide the hæmoglobin of the spleen pulp was almost devoid of contamination with that gas.

RELATION OF THE SPLEEN TO THE SYSTEMIC CIRCULATION.

The quest of the spleen as a storehouse for red blood corpuscles outside the circulation seemed to be worth following in a more systematic manner, and with the assistance of Henry—of the same ilk—I⁵ determined

to find out how long it required for the carbon monoxide to penetrate in spleen, and when and if the carbon monoxide did enter the spleen pulp, how long it remained there after it had been cleared from the general circulation. Our work was continued by Hanak and Harkavy and by de Boer and Carroll. I may deal with the two papers together. The following statements may be made.^{6 7}

1. In rabbits breathing air which contains 0.1 per cent. CO there is a lag of about 20 minutes, more or less, between the time at which the blood contains a certain percentage of CO hæmoglobin and the time at which the erythrocytes in the spleen pulp acquire the same percentage.

2. After the hæmoglobin in the spleen pulp has attained to an equilibrium with that in the blood, if the rabbit be taken out to the air containing carbon monoxide and placed in air free from that gas, the spleen pulp retains the carbon monoxide much longer than the general circulation, so that upwards of an hour may elapse between the time at which hæmoglobin of the circulating blood drops to a certain CO saturation and the time at which the hæmoglobin in the spleen pulp falls to the same saturation.

3. If the animals—cats, rabbits, guinea-pigs, and rats—be placed in air containing a much lower percentage of CO, such, in fact, that the blood in the general circulation does not become more than 20 per cent. saturated with carbon monoxide, the CO may not penetrate at all into the spleen pulp, the hæmoglobin in that situation remains entirely free from the gas for as much as four hours. This phenomenon, which is confined to resting animals, is very important, because it shows that in those animals the spleen pulp is cut off entirely from such circulation as may be taking place in this organ. It shows also that the rhythmic contractions which we are accustomed to associate with the life of the spleen either do not take place during normal circumstances of rest in the body, or if they do, the changes in volume are so small as to trench only on the volume of the blood in the vessels. It is clear that if there were any rhythmic ebb and flow of corpuscles between the circulation and the spleen pulp, the carboxyhæmoglobin must enter the pulp with the corpuscles which contain it.

4. It is the resting animal that I have been discussing; in the active animal it is otherwise. Take up a rabbit by the ears and if it kicks about, as very likely it will, the carboxyhæmoglobin will penetrate at once into the spleen pulp, so that in five minutes the pulp will acquire a percentage of hæmoglobin which five hours would not suffice to give it were the rabbit at rest. The opening of the storehouse door is functional.

MECHANISM OF THE SPLENIC CONTRACTIONS.

5. At this stage something must be said about the mechanism of the splenic contractions. Whilst it is true that CO does not readily enter the spleen pulp, it is also true that a very small quantity of carboxyhæmoglobin in the blood will cause some contraction of, as opposed to peristalsis of, the spleen. This contraction is not the effect of carbon monoxide on the spleen itself, but of carbon monoxide on the central nervous system. It would be more correct to say that it is the effect on the central nervous system of a reduction in the amount of oxyhæmoglobin in circulation. Thus if the spleen of an animal be connected to the rest of the body solely by the nerves, all other connexions being severed, and if it be perfused with blood from an artificial circulation, the spleen will contract if carbon monoxide be given to the animal, but it will not contract as the result of introducing carbon monoxide into the blood with which the splenic circulation is supplied.

Carroll and de Boer made it quite clear that the material wrung from the spleen was largely corpuscles, because the CO content of the blood in the splenic vein, drawn during a contraction, was intermediate

between that of the splenic artery and the spleen pulp—e.g.:

Percentage COHb Content of Hæmoglobin.

	Arterial.	Spleen pulp.	Splenic vein.
Exp. 4	11	0	7
.. 5	15	2	8
.. 6	30	3	13

Let us review the situation up to the point at which we have arrived. We started with the underlying idea that if the body were deprived of blood by a diversion of that fluid to the skin in a warm climate, the blood volume would increase and the necessary corpuscles might be extruded as an emergency measure from the spleen. We have seen that administration of carbon monoxide which reduces the quantity of oxyhæmoglobin in circulating blood will make the spleen contract, and as mere deficiency of oxygen in the inspired air will do the same we are justified in asking whether the spleen is, in fact, a reserve of red blood corpuscles—a place where, if not wanted for the transport purposes of the body, they may be “parked” till some emergency arises which demands an increased number of vehicles of oxygen transport.

THE SIZE OF THE SPLEEN IN THE LIVING BODY.

Yet any suspicion that the spleen can have more than a purely academic function in contributing hæmoglobin from its store to the general circulation raised the question: What size is the spleen? The answer is far from apparent. In any anatomy book some such statement occurs as that the human spleen weighs from 4–10 oz.—i.e., from 110–275 g. But this is the dead spleen. The question is forced upon us: What relation does the bulk of the living spleen bear to that of the dead organ? In search of an answer our group had recourse to the X rays. It is not possible to see the spleen in a radiogram, and, being in no way an X ray expert, I consulted Dr. Dale as to whether at the National Medical Institute he had any experience of methods by which otherwise invisible organs can be thrown into relief. Such, for instance, as the blowing of gas into the abdomen. I would like here to record our thanks to Dr. Dale for a most valuable suggestion—namely, that small pieces of metal might be attached to the edges of the spleen in a preliminary operation and, as their position could easily be seen on the radiogram, an idea of the size of the spleen could be obtained. For the purpose we have used metallic sutures which are easily clipped on to the edge of the organ at suitable points. The operation is very easy; the animals in all cases make rapid and quick recoveries.

Two types of experiment have been carried out by Drs. H. A. Harris, Orahovats, Weiss, and myself.^{8 *} The first may be regarded as preliminary, and have been conducted with a pre-war X ray plant in the Cambridge Physiological Laboratory; the latter, which are much more exact, were conducted in the department of anatomy, University College, London. Fortunately the changes in size are sufficient to give a value to the preliminary series, though one would only accept them in the light of the more exact data. The X ray apparatus at Cambridge only projects rays from below upwards. Consequently in order to get an idea of the position of the sutures in the body it is necessary first to look at the animal when on its stomach and then when on its side. This practice is vicious for several reasons: (1) there is some displacement of viscera in orienting the animal; (2) neither the sutures nor the screen is the same distance from the bulb when the animal is in one position as when it is in the other.

But the method, as a preliminary one, is very convenient for rabbits. It is easy to make numerous observations measuring the distances apart of the suture-shadows on the fluorescent screen with dividers and not the changes which occur by inspection.

* For the success of the results we owe much to Mr. Melville, Technical Assistant in Prof. Elliot Smith's department,

When a definite issue has presented itself the animal was moved up to London and the point proved or disproved by the taking of radiograms by Dr. Harris in the department of anatomy at University College. The installation there admits of $\frac{1}{8}$ second exposures. From the radiograms taken in two planes one can reconstruct the organ in three planes of space.

The investigation of the size of the spleen during life resolves itself into a comparison between the living and the dead spleen. The latter, of course, we can weigh. This comparison has been carried out entirely by orthodiagrams. The following procedure has been adopted. Two radiograms are taken in the lateral and antero-posterior planes, with an exposure of $\frac{1}{8}$ second, one half second being sufficient for the change over from one tube to the other. The animal is then killed in some suitable way; another pair of radiograms are taken shortly after death and a third pair next day. The body is then opened, any adhesions are noted, and the spleen taken out and weighed. From the films prints are made and the following reconstruction takes place. The print from the side (such as those shown in Fig. 1, but of the original size) is laid on a flat paraffin block. Through the point at which the teeth of each suture meet a sewing needle is driven into the wax. This needle is vertical and into the eye is tied a thread. On the view from the back is measured the distance of each suture from the middle line of the animal (or from some convenient line parallel to the middle line) and the needles are driven into the wax until the top of each needle is as

FIG. 1.

A B

Metal sutures indicate the contour of the spleen. A, after mild exercise. B, at rest.

far from the surface of this wax as the corresponding suture is (on the print) from the middle line of the animal. A piece of soft copper wire is now adjusted to the tops of the needles, being tied to each by the thread and so a wire figure is made which delineates the edge of the spleen. This structure of wire is used as a template; from it an area is traced on paper or sheet lead bent to fit its curvature. This area is then cut out and if flattened would represent the surface which the spleen would cover if taken out of the body and laid on the flat. Of course, the alteration in area of this surface, as between life and death, only represents the change in the size of the spleen in two planes of space. There is no reason from the musculature of the organ to suppose that the thickness of the spleen is more or less involved than the length or breadth, and therefore one may form a crude idea of the changes in volume by taking the square roots of the superficial areas of the lead models (or of the weights of the models) and cubing these square roots.

If the weights, as representing the surfaces, are used, of course care must be taken to see that the sheet lead (or paper) of which they are made is of uniform thickness.

Fig. 2 shows a number of such areas taken from the spleen of Cat 1. Of these the first three and the last two are those which concern us. The first two are

A, normal i.; B, normal ii.; C, urethane; D, E, F, hæmorrhage; G, after death; H, following day.

from the resting cat at observed different times, a week apart. The cat was bled to death within an hour or two of taking the second; the last two were after death, one immediately after, the other the day after. Similar records were taken from Cat 2. In each case the post-mortem weight of the spleen was 6.6 g. The following are the calculated weights corresponding to the records. Cats 3 and 4 were drowned (Table I.).

TABLE I.—Weight of Resting Spleen (Grammes).

Cat.	Weight post mortem observed.	Weight just after death computed.	Weight at rest computed.	Mode of death.
1	6.6	6.7	26.4	Hæmorrhage.
2	6.6	6.5	24.1	
3	10.0	11.8	19.8	"
4	12.1	12.3	31.2	Drowning.

In the case of the cats given above it is calculated, therefore, that the spleen in the living cat is two to four times as heavy as that in the cat which has been bled to death or drowned, the loss of weight during the operation being from 10–20 g., a very appreciable fraction of the blood volume, which would be from 100–150 c.cm. To the latter fact I will return; here I emphasise the striking phenomenon that the living spleen may in the cat be four times the size of the "anatomical" or "post-mortem room" spleen and about 1 per cent. of that of the animal.

EFFECT OF HÆMORRHAGE ON SIZE OF SPLEEN.

The mention of hæmorrhage leads us to some other considerations. If the spleen is to be regarded as a sort of bank of red blood corpuscles in which they are stored in large numbers and from which they can be thrown into the currency of the circulation on demand, the spleen should respond to two calls which have not yet been considered; of these the first is hæmorrhage, in which oxyhæmoglobin is removed from the circulation; the second is exercise in which the utilisation of the hæmoglobin is much increased. Let us consider first the question of hæmorrhage. Cat 1 was not bled to death in a single bleeding but in a succession of bleedings and under urethane. Fig. 2 shows the reconstructed "spleen-surface" after each bleeding. In this case the urethane had little effect on the size of the spleen, but on hæmorrhage it contracted down until in the death-agony the spleen was only one-sixth

of its original size. After death it expanded somewhat; presumably the muscular fibres relaxed, but in the absence of any considerable circulation the expansion could not be very great (Table II.).

TABLE II.

Hæmorrhage.	Relative weight of spleen.	Calculated actual weight. Dead spleen = 6.6 g.
0	1000	24.3 g.
10	604	14.5 g.
37	320	7.8 g.
61	167	4.1 g.
Dead.	273	6.7 g.
Next day.	271	6.6 g.

During the hæmorrhage the spleen of Cat 1 shrank from 24.3 to 4.1 g., squeezing out over 20 g. of material. This material, if blood, would correspond to about one-sixth of the blood volume of the cat; if red blood corpuscles, to about one-third of the corpuscles. Quite similar results were obtained on Cat 2.

EFFECT OF EXERCISE ON THE SIZE OF THE SPLEEN.

The picture shown in Fig. 3, taken from Cat 1, show a very simple case of the shrinkage of the spleen with exercise; the photos are taken from the side. It will be observed that this aspect of each suture is nearly the same in both pictures, and therefore evident approximation of the suture-shadows represents, though not quite quantitatively, the approximation of the sutures themselves.

The manufacture of models from these lateral pictures and the corresponding antero-posterior ones taken from the back gives us the second pair of surfaces shown in Fig. 3. The first pair were from

FIG. 3.

Showing reconstructed spleen surface before and after exercise in Cat 1.

Cat 1 a week earlier. Remembering that the dead spleen of the same cat weighed 6.6 g. we can form an estimate of the weights of the spleens before and after exercise. Similar data were obtained from Cat 2 (Table III.).

TABLE III.—Estimated Weight of Spleen.

—	Rest.	After exercise.	Shrinkage.
Cat 1 (a)	26.4	13.7	12.7
„ (b)	24.1	7.1	17.0
„ 2	19.8	9.9	9.9

Here, again, we see that with exercise which was not at all severe the spleen can squeeze out 10–17 g. of something which may be blood, or may even be mostly red corpuscles. In the latter case 17 g. of corpuscles would correspond to about 40 c.cm. of blood, or blood equivalent to about one-third of a quarter of the total blood volume of the cat. Similar but less striking results were obtained from rabbits.

The last specific point to which I shall address myself is this. Can it be shown in point of fact that the possession of a spleen really makes any tangible

difference to the organism? Well, I suppose the greatest difference which anything can make to it is the difference between life and death. Can we, therefore, think out any set of circumstances in which animals without spleens would die where animals with spleens would, on the whole, survive? Such a circumstance might be a certain degree of hæmorrhage, but more easy of experimental proof is a certain degree of carbon monoxide poisoning. Several experiments were performed in which guinea-pigs of three categories were exposed to coal-gas.*

The three categories were: (a) normals; (b) those in which the abdomen had some omentum or pancreas had been removed in the neighbourhood of the spleen; (c) those in which the spleen was removed. In a typical experiment three animals of each category were placed simultaneously in a chamber and the gas tap turned on. The times of death were noted and also the percentage saturation of the blood with carbon monoxide at death. Briefly, it may be said that the fatal percentage of carbon monoxide in the blood of all the guinea-pigs was the same. On the whole the animals in category B died a trifle sooner than those in category A, whilst the splenectomised animals died markedly sooner than either (Table IV.).

TABLE IV.

—	A. Normals (18).	B. Operated controls (16).	C. Splenectomised (17).
Mean percentage of COHb in blood at death. . .	83.3	83.5	83.3
Longevity in gas expressed in a percentage of A ..	100	93	74

Control experiments of another sort were made. The animals were exposed not to carbon monoxide, but to hydrocyanic acid—a gas which does not poison by making a demand on the hæmoglobin in circulation. In this case no difference could be detected between the longevity of the normal guinea-pigs and that of the controls in the hydrocyanic acid.

It is not intended that the views which I have put forward should compete with the current teaching about the functions of the spleen; rather they render it more intelligible. I have no wish, for instance, to deny that the spleen is an important cemetery for red blood corpuscles any more than I have to tilt against anyone expressing the view that London is the largest cemetery in England, but I think that, according to the above experiments, the blood volume should be regarded not as aliquot part of the body-weight, but as a physiological variable which is adjusted to the work required of it, and to the size of the “bed” which it occupies, and of the spleen as being, not a “ductless gland,” but a definite part of the vascular system. It has a function entirely in conformity with its muscular structure, being in fact a reservoir of corpuscles at once fitted by its reticulum to detain them and by its musculature to expel them when required to do so. Finally we are enabled to arrive at an intelligible estimate of when and why the body is likely to “vent its spleen.”

THE TREATMENT OF PURPURA HÆMORRHAGICA BY SPLENECTOMY.

BY G. A. SUTHERLAND, C.B.E., M.D. EDIN.,
F.R.C.P. LOND.,

PHYSICIAN TO THE PADDINGTON GREEN CHILDREN'S HOSPITAL;

AND

BRUCE WILLIAMSON, M.B., CH.B. EDIN.,
HOUSE PHYSICIAN TO THE ABOVE HOSPITAL.

THERE seems to be a considerable difference of opinion as to the prognosis in cases of purpura hæmorrhagica or the *morbis maculosus Werlhofii*. Some view the condition as trifling, others as quite hopeful, and others as often terminating fatally after a more or less prolonged course. There are certain reasons for these discrepancies.

The term purpura hæmorrhagica has been employed by some writers to cover several conditions, and by others to denote one particular type of bleeding disease. Some text-books define purpura hæmorrhagica as an idiopathic disease in which purpuric eruptions are associated with hæmorrhage from a mucous membrane. More modern books use the term to signify an idiopathic disease in which hæmorrhage from mucous membranes and petechiæ are prominent features, and in which the blood shows essentially a thrombocytopenia—i.e., a diminution in blood-platelets. It is only within recent years that any exact differentiation has become possible. With the aid of modern methods of blood examination it has become possible to define one particular type by a combination of clinical history, physical signs, and certain blood tests, and to this type the name "essential thrombocytopenic purpura hæmorrhagica" has been applied by American writers. Despite the obvious drawbacks to such a title, we have adopted it (and shall refer to it in this paper as E.T.P.H.), as it leaves no room for confusion and effectively isolates this from the other forms of purpura. This differentiation becomes a matter of prime importance if splenectomy is to be considered as a method of treatment.

Clinical Conditions.

Thrombocytopenic purpura hæmorrhagica is essentially a disease of early life, although it may occur at any age. It begins commonly between the ages of 2 to 15 years. It would appear to be a primary disease. There is no hereditary tendency, there is no known constitutional or local disease associated with it, and in the acute cases, which tend to a natural recovery, there are no sequelæ. It will be seen that many forms of purpura, those associated with a family tendency and those which are secondary to or associated with some manifest disease, are thus ruled out. The onset is the same as in purpura simplex—namely, the appearance of a crop of purpuric spots or bruise-like marks in some part of the body. In some cases a sudden epistaxis may mark the onset as noted by the patient, but examination at this time will usually show the presence of purpuric spots or ecchymoses in some part of the body.

As many acute cases tend to a natural recovery, with, without, or in spite of treatment, we shall confine our attention to the chronic relapsing cases, which are the only ones in which treatment by splenectomy would be considered. The usual history is one of fresh hæmorrhages recurring from time to time, and lasting for a few days or weeks. Between attacks there are intervals of from a month to three or six months. The hæmorrhage referred to is usually epistaxis. The skin hæmorrhages do not attract so much attention, but they also vary in extent at different times. Hæmorrhage from a mucous membrane does not yield readily to any treatment, and usually ceases spontaneously. In the case of epistaxis

plugging of the nostrils has often had to be resorted to. Direct transfusion of blood may lead to a temporary cessation of the bleeding, but the effect soon passes off, and bleeding of a severe type recurs. Clinical observers have come to the conclusion that in severe cases no reliance can be placed on blood styptics, or sera, or any medical remedies employed in other forms of hæmorrhage. Whatever be the form of treatment the result is the same—the bleeding stops of its own accord, and not as the result of outside agents. It will be found that recurrences of the hæmorrhage take place irrespective of any known preventive treatment, and that these are determined by the alterations in the blood present in and characteristic of this disease. Recurrent, intractable, and often alarming hæmorrhages are amongst the leading features. Oozing about the gums is common, especially when the patient brushes the teeth. Epistaxis is the commonest and outstanding form of hæmorrhage from a mucous membrane. Other sites of hæmorrhage may be in the stomach and bowel, in the kidneys and urinary passages, in the vagina, and sometimes in the brain or meninges.

The onset and progress of the disease are characterised by a singular absence of symptoms of discomfort or ill-health. The patient will probably never complain of anything until the progressive anæmia leads to symptoms. The causes of the anæmia are two-fold, first the underlying changes in the blood, and secondly the loss of blood from recurrent hæmorrhages. Many cases run a prolonged course, lasting sometimes for years, in which, apart from the pallor, languor, tiredness, &c., accompanying the anæmic condition, one cannot find any distinctive symptoms. This absence of symptoms becomes a valuable aid in diagnosis.

On physical examination petechiæ are seen, fresh crops of which come and go. They are usually small and discrete and remain so. We have not met with the larger type of purpuric eruption, such as is common in Henoch's purpura, in which the effusion takes the form of raised hæmorrhagic nodules or urticarial wheals. The petechiæ are most abundant in the lower extremities, but may appear anywhere, often in the mucous membrane of the mouth. Ecchymoses are usually found if the child has been up and running about. The ease with which these ecchymoses are produced from very slight injury and the extent of the resulting hæmorrhage form striking features in this disease. The only other change to be noticed is an enlargement of the spleen. This does not usually attain to any great dimensions and would appear to vary considerably from time to time, and it is probable that an active stage of the disease is accompanied by an increase in size of the spleen, along with an outbreak of fresh purpuric spots and hæmorrhage.

The Blood Tests.

An ordinary blood examination will show the presence of a secondary anæmia varying with the severity of the disease. There are three outstanding features in connexion with the blood which help to differentiate this disease.

1. *A Great Diminution in the Number of Blood Platelets or Thrombocytes.*—In normal human blood the blood platelets average from 150,000 to 300,000 per c.mm. In this disease the number is greatly diminished, falling in different cases to 40,000, 20,000, 5,000, or there may be no platelets at all. This is regarded as so important and characteristic a feature that the term thrombocytopenic has been incorporated in the name of the disease.

2. *Prolongation of the Bleeding Time.*—The bleeding time is determined by puncturing the ear and noting the time during which blood continues to flow. In healthy conditions this will be from two to four minutes. In E.T.P.H. the bleeding time is prolonged to 10 or 12 minutes, and in severe cases may last from 20 minutes to many hours. It is not claimed that this prolongation of the bleeding time is peculiar to

purpura hæmorrhagica, but it is not present in purpura simplex, Henoch's purpura, or hæmophilia. It is rather difficult at first sight to understand why, when the coagulation time is normal, the bleeding time should be prolonged. This difficulty is explained by Duke as follows. Hæmorrhage is not stopped by a clot but chiefly by intravascular plugs (thrombi). A clot is formed from blood at rest and the coagulation of fibrinogen is the essential factor. A thrombus, on the other hand, is formed from blood which is flowing, and for its formation a certain number of platelets is indispensable. Platelets adhere to any injured point in a blood-vessel and are deposited there in enormous numbers by the blood as it flows past, until, finally, thrombosis is complete. It is easily conceivable that an almost entire absence of platelets from the blood should lead to abnormality in the initiation or completion of thrombosis, and be a cause of prolonged hæmorrhage, whether the fibrin-forming elements were normal or not.

3. *Non-retraction of the blood clot* is rather a striking feature. Normal blood will clot readily en masse, and in 20 minutes the clot will be definitely contracting, and within an hour will be firmly contracted and surrounded by the expressed serum. In this disease, while the blood clots in the usual way and in the normal time, no retraction takes place, even if it remains standing for hours. It is evident that some constituent of the blood is lacking—namely, as stated above, the blood platelets. Confirmative evidence of this is supplied by the fact that when the blood platelets reappear in sufficient number in the blood, for example after splenectomy, the clot again becomes retractile and the bleeding time normal.

Diagnosis.

For the exact diagnosis of E.T.P.H., and from the point of view of treatment by splenectomy, it seems advisable that both the clinical phenomena and the blood tests should be found to correspond with the picture outlined above. The recorded cases which have been successfully treated by splenectomy show a great similarity in clinical history, clinical findings, and blood reactions. There is no single symptom or blood test peculiar to this disease. It is the symptom-complex which enables one to differentiate the special type, and when an operation like splenectomy is on trial for one form of hæmorrhagic disease it seems very necessary to limit its application to that type and not to employ it indiscriminately for other forms of purpura.

Pathology.

Recent studies on purpura hæmorrhagica have thrown some fresh light on the old problems. It has long been disputed whether a purpuric eruption was due primarily to an altered condition of the capillaries or to an altered condition of the blood. The escape of blood from the capillaries, with or without slight traumatism, was supposed to indicate an underlying friability or permeability of these vessels. In the case of E.T.P.H. it is clear that the prolonged bleeding time and the absence of clot retraction cannot be dependent on any changes in the vessel wall. That an abnormal permeability of the capillaries is present in E.T.P.H. is shown by the capillary resistance test. This consists in applying a tourniquet for a couple of minutes round the upper arm with a pressure sufficient to lessen, but not entirely stop, the flow of blood in the arteries. In a few minutes a crop of petechiæ appears over the limb below the constriction.

Probably the outstanding factor amongst the blood changes is the diminution in the number of blood platelets, the so-called thrombocytopenia. The fact seems to be that if the blood platelets are reduced below 40,000 per c.mm. in place of the normal 150,000 to 300,000, a tendency to purpura is at once produced, and is increased as the platelets diminish further in numbers. The presence of a sufficient number of platelets seems to be necessary to prevent

capillary leakage (petechiæ) and also in connexion with the normal clotting of the blood. Hence in E.T.P.H. the prolonged bleeding time and the non-retraction of the clot are supposed to depend on some constituent of the blood, which has been removed with the platelets, and which is probably produced by the platelets.

The importance of a sufficiency of blood platelets has been shown experimentally. Duke was able to produce the clinical signs of purpura hæmorrhagica (petechiæ, prolonged bleeding time, and non-retractile clot) in rabbits by reducing the platelet count with diphtheria toxin. In the treatment of cases of purpura hæmorrhagica by direct transfusion it has frequently been found that the hæmorrhages ceased coincidentally with an increase of the platelet count. Hæmorrhage recurred when the platelet count fell again, usually a matter of a few days. It seems now to be generally accepted that a condition of thrombocytopenia is directly and causally associated with purpuric manifestations. The recognition of this association does not imply the acceptance of any extreme views, such as that the sole cause of purpura is a thrombocytopenia or that purpura hæmorrhagica is invariably accompanied by a small platelet count. The one point of progress in the pathology is the differentiation of a type of disease—namely, thrombocytopenic purpura hæmorrhagica.

Another advance in our knowledge was the recognition of the fact that the spleen played a part in the production of E.T.P.H. So far no one has been able to prove that the spleen has any beneficial function, nor have bad effects been traced to its removal in certain forms of disease. On the other hand, we have now much evidence of the evil results following on disease, or, to be more precise, disordered action of the spleen. In splenic anæmia and in acholic jaundice we have examples of disordered action of the spleen. This action takes effect on the blood and is of a destructive character, affecting more especially the red cells and the hæmoglobin. In E.T.P.H. there seems to be another type of disordered action in the spleen, which takes effect more especially on the thrombocytes and leads to a great diminution in their number. Whether the platelets are actually destroyed by the spleen or are merely withdrawn from the circulation and stored up in the spleen seems still uncertain. In some cases of splenectomy for E.T.P.H. the blood in the spleen has been found to contain many more platelets than red cells.

It may naturally be asked, Why incriminate the spleen in connexion with these blood platelet changes and purpura hæmorrhagica? A bold man, Frank of Berlin, held the view that the spleen inhibited the formation of platelets and suggested its removal in purpura hæmorrhagica. A bolder man, Kaznelson of Prague, was of opinion that the spleen destroyed the blood platelets in purpura hæmorrhagica and proceeded to remove it. His patient was completely cured of all symptoms and has continued well. In the United States, Brill, Rosenthal, Murray Bass, Cohen, and others, have employed splenectomy in this disease with excellent results. It has been proved by these workers that whatever the exact rôle of the spleen may be in E.T.P.H. it certainly is a very important one.

The whole subject of the relationship between E.T.P.H., the blood platelets, and the spleen requires further elucidation. It is not definitely known whether the spleen (1) inhibits the bone marrow formation of platelets (Frank), or (2) removes the platelets from the circulation (Kaznelson), or (3) alters the nature and agglutination properties of the platelets (Brill), or (4) removes abnormal platelets produced by abnormal megacaryocytes (Seeliger). It is clear that the spleen is directly associated with the great diminution of platelets in the blood in thrombocytopenic purpura hæmorrhagica, because after splenectomy they soon reappear in normal numbers, and there is also found a restoration of the normal bleeding time and clot retraction. The fact that the spleen is enlarged in

this disease can usually be made out on clinical examination and is always evident when splenectomy is performed. So striking have been the results of splenectomy in E.T.P.H. that the duty of pathologists now is not to question the direct action of the spleen in this disease, but to determine the exact change or disturbance in the spleen leading to thrombocytopenia, and also its cause.

Treatment by Splenectomy.

So far as we are aware no cases of purpura hæmorrhagica treated by splenectomy have been recorded in this country. The following cases have been under our care recently, two of which were considered suitable for splenectomy. A study of the literature of the subject shows that the operation is by no means devoid of risk in this disease. The physician ought to have sufficiently clear indications for splenectomy and see that the time selected is the best for the patient. In the two cases operated on it was considered that the general health of the patient was suffering, and that radical treatment was required. Both patients had suffered from severe recurrent epistaxis, one for six months and the other for three years, and were confined to bed owing to the anæmia and debility. At the time of operation there was no active epistaxis or other internal hæmorrhage going on. It certainly seems advisable, although it may not be necessary, to operate during an interval between the recurring attacks of active bleeding. The presence of petechiæ and the tendency to bruising do not seem

CHART 1.

Operation, June 19th, 1924.

to be of prime importance, as they are more or less constantly present. As all forms of active movement tend to increase the hæmorrhage, it was considered advisable to give the patients a month's rest in bed before the operation. Transfusion of blood seems to

be regarded in America as a useful preliminary, but we did not employ it. The third case was not considered suitable for operation because active epistaxis had ceased for nine months and the general condition was satisfactory. In the recorded cases of operation the platelet counts vary considerably, and some

CHART 2.

Operation, July 3rd, 1924.

writers describe a fall to the previous low level after a temporary rise. In our cases, as shown in the charts, the number of platelets rose markedly after operation, and never reached the former low level. All the blood examinations in our cases were made by Mr. Herbert Perkins, who used Bedson's method for the platelet count.

Case Records.

CASE 1.—E. B., female, aged 8 years, presents a typical history of purpura hæmorrhagica. She first came under notice in July, 1921, for profuse epistaxis and hæmatemesis which occurred spontaneously without any antecedent symptoms. Prior to this abrupt onset there had been no actual hæmorrhage, but a tendency to be easily bruised is said to have existed for some time. The chronicity of the disease has been an outstanding feature, and we have records of nine admissions to hospitals for serious hæmorrhage with collapse during a period of three years. Remissions undoubtedly did occur, as is evident from the condition of the blood in March, 1923, in the second year of the illness (vide Chart 1). On many occasions her condition was extremely grave, and so precarious was it from January to June of last year that she was bedridden in hospital on account of repeated hæmorrhages.

Petechiæ and ecchymoses have been constantly present, occurring in crops in the skin and mucous membrane of the mouth. Large extravasations have been found in the loose tissues of the eyelids, and on one occasion a spontaneous subconjunctival hæmorrhage took place. The retinæ have never been involved. The purpuric rash could not be detected by touch, and no urticarial element has been noted. Epistaxis and hæmatemesis constituted the grave

dangers. During the first half of last year severe epistaxis occurred about every third week, hæmatemesis was less frequent, melæna was a common finding, but the urine was always free from blood. The resultant anæmia was essentially of the chlorotic type (Chart 1). The hæmoglobin was often reduced to 40 per cent. The red cell count always maintained a high level despite the depletions by hæmorrhage, and this indicated a vigorous erythroblastic reaction in the red marrow. In type the red cells were immature. The most striking feature of the blood was the marked thrombocytopenia, the highest count being 18,000 per c.mm. Evidence of the anæmia was present in the generalised pallor, to which was added a definite yellow tinge, well seen in the conjunctivæ. Much soft subcutaneous fat was present all over the body. Fatigue and dyspnœa were easily induced.

The diagnosis presented no difficulty. No cause for the hæmorrhages could be discovered. The spleen was usually palpable with ease and varied considerably in size. Hæmophilia could be definitely excluded. The special characteristics of the blood in purpura hæmorrhagica were all present and constant: (1) thrombocytopenia, (2) prolonged bleeding-time (about ten minutes), (3) clotting-time normal with non-retractile clot, and (4) capillary pressure test positive.

In June of last year the patient was transferred to us from an infirmary where she had been confined to bed for six months. Her condition was extremely serious. Epistaxes had been so numerous that a nasal plug was practically always in use. Her resistance to infection was very low. There were excoriations about the nares, styes were present on the lids, and the teeth and gums were in an unhealthy condition. A state of chronic invalidism was established.

On June 19th, 1924, splenectomy was performed by Mr. John Murray. The loss of blood at the operation was no greater than normal. The recovery was uneventful and healing occurred by first intention, the scar later showing keloid characteristics (as in Case 2). The spleen weighed two and a half times the normal and externally presented a normal appearance; on section the Malpighian corpuscles were prominent to the naked eye. Microscopically the striking features were the great diminution in the number of lymphocytes, and the marked endothelial proliferation in the Malpighian bodies and the sinuses. The connective tissue of the sinuses was swollen and hyaline. Blood platelets were not in evidence.

The present condition of the patient shows a remarkable improvement in her general health, and she now leads the ordinary active life of a child with her family. The yellow tinge in the skin and watery fat are no longer evident. No external hæmorrhage in any form has occurred since the operation five and a half months ago. Petechiæ and bruises still occur but to a less extent than formerly. The blood condition as indicated on the chart steadily progresses to the normal. The bleeding-time is about two to three minutes and the clot contracts firmly and expresses clear serum.

CASE 2.—H. R., male, aged 9 years, presents a shorter history than the previous case. He was a perfectly healthy, sturdy boy until December, 1923, when the disease first made its appearance. The initial symptom was the development of a tendency to bruise readily on the slightest injury. Inquiry failed to disclose any constitutional disturbance of any kind. Since the onset the patient has been under constant medical supervision and has spent most of his time in hospital.

During the first two months of 1924 the disease was at its height. He became subject to spontaneous hæmorrhages in the form of epistaxis and purpuric manifestations. Melæna was a frequent finding and hæmatemesis occurred on three occasions. Petechiæ and ecchymoses, presenting the same characteristics as described in the previous case, became constant and prominent features in the skin and mucous membrane of the mouth. The retinæ showed no involvement. Profuse epistaxis at times proved very intractable to treatment, and occurred every second or third day. Within a month of the onset the patient was profoundly anæmic. The red cells were reduced to $1\frac{1}{2}$ millions, and the hæmoglobin was down to 20 per cent. His condition was extremely grave and caused much anxiety. Complete rest in bed was essential.

The succeeding three months saw a gradual amelioration. The intervals of freedom from hæmorrhage steadily increased from days to weeks, and he was able to take moderate exercise. The danger of hæmorrhage was always present and necessitated very careful supervision. The blood condition improved greatly, especially with regard to the red cells as indicated on Chart 2. A careful examination

failed to locate any source of infection. The spleen was found to be moderately enlarged and easily palpable at the left rib margin. The mouth was rendered more healthy by the extraction of carious teeth, and the sinuses were thoroughly examined for signs of sepsis with negative results. Cultures from the faeces produced no significant factor, and intestinal parasites were not found.

Hæmophilia could be eliminated. Repeated examination of the blood revealed all the characters of purpura hæmorrhagica: (1) The thrombocytopenia was very marked; (2) clotting occurred in the normal time of five minutes, the resultant clot being ill-formed and non-contractile; (3) bleeding-time was prolonged to 12 minutes. The capillary pressure test in this case gave negative results. Externally he exhibited the same appearance as the previous case. A definite yellow tinge in the skin and conjunctivæ and much soft, watery adipose tissue were present. Petechiæ and ecchymoses occurred daily in large numbers. No serious loss of blood had taken place for a month. Fatigue and dyspnœa were readily induced by slight exercise and his activities were greatly curtailed. The blood condition showed a steady increase in his red cells, the other features remaining unchanged.

Splenectomy was performed on July 3rd, 1924, by Mr. John Murray. The operation was entirely successful and, as in the first case, there was an absence of any excessive bleeding. Convalescence was interrupted by an attack of acute appendicitis, which was treated by operation. Both scars later showed keloid characteristics. The morbid anatomy of the spleen, which was enlarged to three times its normal size, showed changes identical with those described in the previous case. Thrombocytes were not in evidence. A lymph gland removed from the mesentery at the time of operation also exhibited marked endothelial proliferation.

The general health of the patient is now excellent, and he has returned to the normal active life of a boy of his age and attends school again. Despite the loss of much fat, his weight has increased by 2 lb. No hæmorrhage in any form has occurred since the operation five months ago. The skin has been free from any purpuric manifestations and the bruising tendency has entirely ceased. The blood now fails to show any feature characteristic of purpura hæmorrhagica. The bleeding-time is normal and the clot contracts well and expresses clear serum. Thrombocytes showed a striking increase immediately following the operation, and this has been maintained.

The results in this second case are even more striking than in the first. All signs of the disease appear to have been eradicated. The charts accompanying these two cases show more clearly than any detailed description would do the changes in the blood which are common in this disease, and more especially the effects of splenectomy on these changes.

CASE 3.—Z. H., female, aged 13 years, was apparently a perfectly healthy child of normal development until she reached the age of 4, when, without any prodromal symptoms, she developed a marked tendency to bruise easily. Within a few months the additional symptoms of purpura which was very profuse and frequent epistaxis became features of her condition, and a profound anæmia soon became established. The condition of the blood, one year from the onset, showed red cells diminished to 3,030,000 and hæmoglobin down to 40 per cent.

The next four years saw many instances of grave collapse from hæmorrhage, and her history is one of numerous admissions to various hospitals as an emergency case. On one occasion she was detained for three months owing to repeated severe epistaxis. A condition of chronic invalidism set in with serious effect upon her schooling. The ever-present danger of hæmorrhage precluded her from leading a normal child life, and during the last four years she has attended a special school, an ambulance being used for her conveyance. Bleeding occurred as profuse epistaxis, and we have records of hæmatemesis on one occasion only. Melæna and hæmaturia were never found. Petechiæ in the skin and mucous membrane and larger subcutaneous extravasations of blood have been remarkably constant features since the onset of the disease over eight years ago.

No treatment apart from local hæmostatics has been of any benefit. Thymus, calcium lactate, human and horse sera have all failed to influence the fundamental cause, and transfusion performed on two occasions brought only temporary relief. During the last two years there has been decided improvement as regards the hæmorrhages, which are now less severe and not so frequent. The last attack of epistaxis occurred about nine months ago. The same improvement cannot be recorded with regard to the purpuric rash and the tendency to bruise easily which are still in evidence.

The classification of this case of hæmorrhagic disease presents no great difficulty. The sex and complete absence of any known diathesis in the family history precludes hæmophilia. The blood picture and tests conform in the main to those of purpura hæmorrhagica. Only two complete blood records in this case are available, both taken recently. The thrombocytes numbered 100,000 and later 55,000 per c.mm. The bleeding-time varied from six to ten minutes, and the coagulation-time was found to be normal with good clot retraction on each occasion. The capillary pressure test gave negative results. The red cell count was normal and the colour-index 1. The prognosis would appear to be decidedly hopeful, as there are numerous indications, clinical and otherwise, that the disease is gradually subsiding. The profound anæmia has given place to a healthy appearance, with a blood picture which is practically normal, and which bears only traces of the features upon which a diagnosis of thrombocytopenic purpura is based. Clinically, apart from the bruising and the purpuric rash which are never totally absent, the patient is in good health, and despite the chronicity and severity of the disease in the past, her development is about average, both mentally and physically. Under our advice she is to attend an ordinary school, and the future appears to hold the promise of complete recovery unaided by any active treatment.

THE PREVENTION AND TREATMENT OF POST-OPERATIVE PULMONARY EMBOLISM.¹

By E. C. LINDSAY, C.B.E., F.R.C.S. ENG.,
ASSISTANT SURGEON, THE LONDON HOSPITAL.

THERE is a growing belief that the post-operative lung complications such as pneumonia, pleurisy, and collapse, which have been an endless source of contention and mutual reproach between surgeon and anaesthetist, are not the simple matter of either irritation or congestion and infection that has been alleged. Wharton and Pierson, in the *Journal of the American Medical Association* in 1919, gave it as their considered opinion, after the investigation of 1600 gynæcological operations, that 40 per cent. of cases of pleurisy and 12 per cent. of cases of pneumonia after operation were in reality cases of pulmonary embolism and infarction.

It would be as well at this stage to point out that the size of the embolus is the important factor, and, depending on this, we may distinguish (a) the classic type of massive embolism, occluding one or other pulmonary artery, or bestriding the bifurcation and obstructing both (more usually the right is affected, as Rupp has shown); (b) the infarction type, with severe onset followed by pleurisy and signs of consolidation; (c) the type where the site of the embolus prevents recognition as an infarction on the inner surfaces of the tubes. This type is associated with slight respiratory increase, a slight evening rise of temperature, and the bringing up of small collections

of blood and mucus. There is but little mention in English surgical literature of this last type, but De Quervain, Wharton and Pierson, and Lee all recognise its significance and its warning of the more severe types. Two cases of my own illustrate this condition.

The first case—one of duodenal ulcer—was a man of 52, upon whom a gastro-enterostomy was performed. On the fifth day he brought up a little blood and mucus, as he described it, "from the back of the throat." There was no pain in the chest on deep inspiration, but his temperature swung to 99.4° F. for two or three nights. His chest was examined on two or three occasions by a physician, and no physical signs could be detected. We contented ourselves with the old story of a tuberculous focus temporarily lit up (an illusion which I recall in my house surgeon and registrar days as being a commonly cherished one and covering a multitude of sins!). The whole disturbance quieted down, the patient was up and about, when on the eighteenth day he had an urgent desire to defæcate, intense dyspnoea and cyanosis, and expired in five minutes with all the signs of massive embolism.

To digress for a moment, it will be noted that this patient had a sudden desire to defæcate followed by the signs of embolism. My experience has been that this is a common premonitory sign. The ward-sisters at the London Hospital who see these unfortunate accidents occur, state that it is much more commonly the case for a patient to call for a bed-pan and fall back dying, than to have the attack while actually on the pan. The only explanation I can offer is that the clot, moving up from the femoral or iliac vein, sets up a vaso-motor reflex (or it may be a congestive effect) in the sigmoid, which the patient interprets as a need for evacuation of the bowels.

The other case is in a ward at London Hospital at the moment; a man of 26, whose gangrenous appendix I removed, and who went on well until the ninth day, when he brought up the same type of collections of blood. There was no disturbance of the chest at all in this case; my corresponding physician failed to detect any signs, although he knew my suspicion. The evening temperature was swinging up to 100° F. On the thirteenth day definite signs of thrombosis of the veins of his right calf were detected.

Sir Charles Gordon-Watson emphasised the importance of this slight rise of evening temperature; Wharton and Pierson gave it as a constant premonitory sign. Such a type is not common, yet its origin is presumably the same as that of the massive type (a). I would reiterate once again that deciding factor, the size of the embolus, in its relation to the result produced.

On looking hurriedly through the literature I was struck by the absence of any really large collection of cases, and also by the fact that there was a general tone of alarm at the increase in the frequency of the condition, an alarm which I hope to show later there is no real ground for. I therefore had recourse to the records of the London Hospital on the subject of the massive embolic type (already referred to as type (a)) and found that certain cases of pulmonary infarction (type (b)) were also included under this heading. I began by taking all cases of pulmonary embolism in the surgical records from 1914 to 1924, and found that the total for these years was 152, but as the notes for the war years, 1914-18, were scanty and not altogether reliable, and the proportion of autopsies to deaths very much lower, I excluded 38 cases occurring in those years, leaving 114 cases.

Incidence.

It has been a matter of comment that the condition is on the increase. I certainly shared the impression when in one year among my private patients I had two cases of infarction and one of massive embolism, all three perfectly clean cases. And I notice that Sir Charles Gordon-Watson had a similar experience.² Some surgeons state that about 1916 they began to notice the increase in these tragic complications of operative surgery. In the war we saw practically none

¹ Being a contribution to the discussion at the Royal Society of Medicine reported on p. 333.

² See THE LANCET, 1924, ii., 345.

of them, and the reason is clear now that it is generally recognised, as Mr. Lockhart-Mummery has stated in his address³ to the Section of Surgery at the B.M.A. meeting in Bradford, that sepsis is only an incident in its production, and that the principal factor is venous stasis in patients of advancing years. One eminent physiologist has advanced the theory that there has been a change in blood character and coagulability, possibly depending on national food. About 1916 we were certainly feeling the full force of the importation of foreign albuminoids, such as Chinese eggs and American bacon. Certainly the figures over the whole 11 years would indicate that the numbers are greater since the war; at the same time, the numbers of each year since the war remain about the same. It is probable that the old diagnoses of sudden heart failure and shock after operation included a fair proportion of massive embolism cases.

In the series presented here, there are five fractures, three carcinoma cases, and one prostate case, in none of which operation was performed. There were, in addition, nine cases of sepsis, carbuncles, abscesses, &c., in which simple incision only was made. The post-operative list is thereby reduced to 96 (and this, I think, may be accepted as the mortality from this source) in 31,426 operations for the years 1919-24, which works out at 0.3 per cent. This agrees fairly closely with Rupp's figures published in the *Berlin Archives of Clinical Surgery*, March 21st, 1921. He found, as the result of the investigation of 22,689 operations from 1903 to 1920 inclusive, a mortality of 0.26 per cent. from pulmonary embolism, a difference of only 0.04 per cent., or 1 in 2500. From the figures of 1919-24 at the London Hospital we may fairly conclude that its frequency remains much the same. It must be remembered, however, that with the large increase in the number of operations performed, the absolute mortality to pulmonary embolism will naturally rise.

Lest it should be thought that surgery is mainly responsible for cases of pulmonary embolism, it is of interest to recall here the collateral figures which were published by Rupp from 13,000 autopsies over the same period of 18 years. He found that the mortality from pulmonary embolism in internal disease without operation worked out at 1.1 per cent.—that is, four times as great as that following operation.

The Age Factor.

On analysing the series on this point, a highly important fact emerges—that is, that massive embolism is a disease of later life. The average age for this series was 52; for some diseases it was higher. The urinary bladder and prostate operations worked out at 60. Even appendicitis cases showed an average age of 40.4 years, and, considering there were included three cases whose ages were respectively 2½, 11, and 13 years, the average age of the remainder can only be considered as a very late age for acute appendicitis to occur. The average age of cases of hernia suffering this complication was 53.

If, further, we examine the frequency in different types of operations (and I may say here that the short time at my disposal has not allowed of the complete analysis of 31,000 operations) we find that in stomach operations 21 occurred in 2778 operations; in major gynaecological operations (excluding obstetric cases) 22 in 2004; in appendix cases 17 in approximately 4000, and hernia 12 in 1967. In other words, as in other published series, gynaecological operations head the list. All groups show that it is the older cases in which this complication occurs. This may be some explanation of the apparent increased frequency, as there is no doubt, with the perfected technique and team-work of recent years, age has not been considered the great contra-indication to operation that it once was.

Site of Thrombus.

Post-mortem examination has revealed thrombosis in 42 per cent. of cases in the veins of the pelvis and lower extremities, 50 per cent. of which were in the left iliac or left common iliac vein. Wharton and Pierson agree with this when they state that 41 per cent. of cases are associated with femoral phlebitis. In gynaecological cases, thrombosis of the pelvic, iliac, and femoral veins was found in 47 per cent., and in the stomach cases thrombosis of similar veins was discovered in 57 per cent. of cases. It can definitely be said that this is lower than would have been the case if full post-mortems had been allowed, and not the abdomen only, as is so often the case in death after abdominal operations. I have mentioned these two types of operation, specially as one is portal and the other systemic. In none of the notes of the post-mortems examined was there any mention of extensive thrombosis in the area of operation. In many of the cases crossed thrombosis occurred. As has been noted above, the left common iliac vein accounts for 50 per cent. of the cases in which a thrombus was discovered. Presuming that stasis is one of the most important factors, with the sigmoid and the rectum emptying themselves irregularly, or with the aid of enemata, it is possible that there is a greater stasis on the left side. The less direct drainage of the left common iliac vein may be a further factor. The time when embolism took place after operation in this series averaged out at the tenth day for stomach, appendix, &c.

The Anaesthetic.

As the operations were practically all carried out under general anaesthesia, ether or its mixtures, I have no information as to the effect of anaesthesia. The question of primary pulmonary thrombosis has been discussed at length by Prof. Glynn, and commented on by Mr. Lockhart-Mummery and Sir Charles Gordon-Watson.⁴ Prof. Glynn claimed that of his 35 cases death was due in 30 to primary pulmonary thrombosis. While admitting that it may be responsible for a certain proportion of cases of sudden death after operation, and more especially by cerebral emboli, I think it is difficult to reconcile the high percentages of known sources of thrombi in this series with such an explanation. The size of the thrombus, similar to that of the big femoral or iliac veins, its frequently unbranched appearance, its considerable length (as much as 8 inches in one case and of very nearly equal diameter throughout), the fact that it is nearly always rolled up, seem to me to be strong arguments in favour of a thrombus formed elsewhere than in the lungs. Rupp says the embolus is nearly always in the right lung. Finally, the pulmonary artery, though carrying venous blood, is arterial in type to support the pressure of the ventricle, and it would seem unusual for a thrombus to be loosened and advance against the blood-stream. The experience of all, I think, goes to show that the embolus is loose and coiled up. It has a thin external shell of lamination, and a core of red unorganised clot.

Summary.

(1) There is no evidence, from a consideration of statistics, that the condition has relatively increased. (2) Age is a most important factor in its production, the average age in the series being 52 years. (3) The primary thrombus formation occurs in the veins in which there is marked stasis—namely, the pelvic and femoral veins. In this series, in 42 per cent. this thrombus was discovered. (4) Sepsis is probably only a contributory cause, acting by lowering the vitality of the patient, and therefore promoting stasis. Why thrombosis should occur in conditions of stasis in the aged and not in the young, seems to me to be a problem for the physiologist rather than for the surgeon, and when that has been discovered we shall be nearer to a method of prevention of this complication.

"POST-ANÆSTHETIC" VOMITING.

By J. D. MORTIMER, M.B. LOND., F.R.C.S. ENG.,
SENIOR ANÆSTHETIST, THROAT HOSPITALS (GOLDEN SQUARE
AND CENTRAL LONDON); HON. SURGEON-ANÆSTHETIST,
ST. PETER'S HOSPITAL.

It is now nearly 15 years since a surgeon's remark led me to make careful inquiry into the after-condition of upwards of 1000 patients to whom I had given anæsthetics, excluding only short cases.¹ The results were as gratifying as unexpected, for I found that in about three-fifths (including many administrations lasting an hour or longer) there was no after-sickness, and it was inconsiderable in the majority of the rest—there having been only 23 (about 2 per cent.) in whom it was continued or severe. As every variety of patient and operation had been comprised, and no special methods employed, my conclusions were as follows:—

1. Whilst it can by no means be denied that an anæsthetic badly selected or badly given may be the direct and sole cause of severe after-vomiting, sickness even to a slight extent is *not* necessarily a result of an administration, and should not occur in a marked degree unless there are conditions which have exaggerated its effect or independently caused the disaster.

2. That severity of vomiting is *not* in proportion to mere length of administration, but depends mainly on the individuality of the patient, the nature of the operation and of the disorder for which it is done, and after-complications.

3. That when it occurs, instead of assuming that the anæsthetic is answerable, other possible causes should be carefully considered and the anæsthetic only admitted as such by a process of exclusion.

It seems advisable again to draw attention to the subject, for the experience gained during this period has confirmed my conclusions, but, judging from discussions and recently published books, its practical importance has not been realised either by surgeons or anæsthetists. In my former articles I gave full statistics and other details, to which I beg leave to refer those who are interested in the question. In these I also considered the causation and management.

In regard to individuality, I should like to quote from a paper by my former teacher, Sir D'Arcy Power²: "Just as some people are always sea-sick or train-sick while others are not, so some always vomit after an operation and others do not." Personal peculiarities unquestionably cause remarkable differences in behaviour during induction, and it cannot be expected that after full anæsthesia has been endured an abnormal person—whether sensitive, overfed, or otherwise—will make a normal recovery.

The Effect of Some Operations and Complications.

It has always been recognised that the functional importance of any structure or organ, and its anatomical and physiological connexions, materially affect, after an operation upon it, certain results, e.g., pain and spasm; but there has been a curious inability to recognise—one may venture to say a reluctance to admit—the extent to which gastro-intestinal and pulmonary complications may be thus produced. If one considers that the viscera in or adjacent to the upper abdomen are not only of much and continuous functional importance, with far-reaching connexions, but are also in close relation with the diaphragm, the action of which has been shown to be temporarily inhibited by an operation in its region,³ one would expect gastro-intestinal atony and nausea to follow, for example, one on the kidney much more than one on the uterus, and such I found to be the case.

I have been told that the late Mr. Clinton Dent, in his lectures on surgery, used to say that sickness always followed removal of the cervical glands; this confirms a statement made to me by the matron of a children's hospital. If in the course of a mastoid operation the labyrinth is touched, retching is liable to occur at once, although the anæsthesia is deep enough to prevent it during other proceedings, and it is liable to occur afterwards if this structure is involved.

I have many times been asked to see patients in whom sickness after an anæsthetic was taking place to an abnormal extent, with which it was agreed after discussion the anæsthetic had little or nothing to do. For instances: in a girl, found in an over-heated, ill-ventilated room, menstruation had come on a few days before expected, and her relatives stated that she was "always bad and often sick" at these times. A lady complained also of an unpleasant taste and smell; after removal of iodoform packing from a cavity in the jaw there was no more sickness. Examination with the ophthalmoscope at my suggestion after operation on a mastoid gave evidence of commencing thrombosis of intracranial sinuses, from which the patient died a day or so later. After an abdominal operation (by a surgeon now deceased) there was much vomiting, for which the anæsthetist (not myself) was blamed; some stitches gave way, and an anæsthetic for replacing them was needed; it was then discovered that the first operation had been an incomplete one.

A physician called to deal with acute vomiting attributed to an error in diet would hardly risk making a serious mistake by accepting such an explanation without further inquiry and strict examination. Post- (non ergo propter-) anæsthetic disorders may, like fatalities under anæsthesia, be due entirely, in part, or not at all to the anæsthetic.

The Need for Preparation and Diagnosis.

The result of an impression still prevalent—that vomiting usually and inevitably follows the inhalation of an anæsthetic (except a momentary one of nitrous oxide) is that prevention and treatment are too often perfunctory and ill-directed.

If it were possible to insist that all patients before operation should submit to appropriate general and special preparation, instead of, as is not unusual, entering a hospital or nursing-home "overnight," there would often be saving of time, trouble, expense, and even danger. In subjects of various forms of malnutrition, auto-toxæmia and neuroses, after-effects are apt to be out of all proportion to the length or gravity of the operation. Although we are still without certain knowledge of "acidosis" or "post-anæsthetic toxæmia," it seems established that, whilst an anæsthetic (and especially chloroform) may be the determining cause, it depends also on antecedent conditions which may be to some extent remediable.

It is unfortunately the case that some authors of books on anæsthetics fail to urge that, when after-vomiting is excessive, all possible influences must be taken into account, and if the "personal idiosyncrasy" cannot be eliminated there must be discrimination between its many varieties; thus one may aim at a rational plan of treatment, instead of that admitted to be "purely empirical" and "usually somewhat unsatisfactory": and by repeating a stereotyped list of sedatives and domestic remedies which "have been tried with apparent success at one time and failure at another," as commonly happens when treatment is nothing but symptomatic.

In conclusion, it may be remarked that anæsthetists, especially Dr. Dudley Buxton,⁴ have urged that better opportunity should be afforded them than is usually arranged for examination of the patient beforehand. It is equally if not more desirable, that

¹ THE LANCET, June 17th, 1911, and Oct. 25th, 1913.

² Practitioner, July, 1920.

³ Pasteur: Medical Society of London, May, 1911.

⁴ THE LANCET, August 6th, 1910.

when there is an unsatisfactory condition afterwards, for which the anaesthetist may be held blameable, or it may be, legally responsible, he should, in conjunction with the operator, investigate the circumstances and advise as to management. By fuller coöperation these disorders will be better understood and more often avoided, or, if they must happen, more effectively treated. The anaesthetist's responsibility will be increased rather than diminished, because it will be more accurately defined.

TYPES OF TUBERCLE BACILLI AND THE EPIDEMIOLOGY OF PHTHISIS.

By G. R. ROSS, M.B., D.P.H. ST. AND.,
LECTURER IN BACTERIOLOGY, LEEDS UNIVERSITY.

THE statistical inquiry into the epidemiology of phthisis pulmonalis in Great Britain, conducted by Brownlee, and published in the Special Report series of the Medical Research Council, is perhaps one of the most arresting studies of the disease in recent years. As a result of the investigation, Brownlee succeeded in demonstrating three clear-cut statistical types of the disease.

The first of these, the "young adult" type, shows a maximum mortality in males between the ages of 20 and 25 years; the second, the "middle age" type, exacts its maximum toll, in males, between the ages of 40 and 45 years; while the third, the "old age" type, has its maximum mortality in males between the ages of 55 and 65 years. The distribution of these types is unequal throughout the country, but there are districts in which each of the "elementary" types are found in characteristic form. Thus in Shetland, and to a lesser extent in Ireland, the "young adult" type is prevalent, in London the "middle age" type, and in Cornwall the "old age" type.

Brownlee, after most exhaustive inquiry into the meteorological, geological, sociological, and industrial factors which may account for the unequal distribution found, advances two possible explanations for their occurrence. The first suggestion is that there are "two distinct strains of tubercle bacilli, each having a special age-distribution. One of the strains attacks in early manhood and possibly also in old age, the other in childhood and middle life." The second explanation is that "the physiological response to attack by the organism may be different according to the environment in which the individuals attacked have lived." He is not, however, prepared to accept either explanation as wholly sufficient to account for all the phenomena of the disease, and considers the "double origin" of the disease as more probable.

The first hypothesis throws out a challenge to bacteriological research. In recent years much advance has been made in the bacteriological study of pneumonia and epidemic cerebro-spinal meningitis by the demonstration that "types" of each of the organisms responsible for these diseases exist. The resulting improvement in the efficacy of the specific treatment of these diseases suggests that were the existence of "types" to be demonstrated among tubercle bacilli there might be hope of a corresponding improvement in the specific treatment of tuberculosis in addition to the confirmation of the statistical hypothesis.

It is not merely the demonstration of the classical "human" and "bovine" types of tubercle bacilli that is required, for the part played by these in the aetiology of the clinical forms of the disease has been fairly definitely established. Brownlee deals only with phthisis pulmonalis, and as this is practically always due to the "human" variety of the bacillus, it follows that the "types" postulated by Brownlee must exist therein. It would perhaps be better to speak of them as "groups," in order to avoid the confusion which might arise in view of the already existing use of the

term "type" to denote the human and bovine varieties of the bacillus.

Attempts to demonstrate such groups have been few in number. Many difficulties have to be overcome, the chief of which is probably the difficulty of preparing a uniform non-granular suspension of tubercle bacilli. Owing to its fatty and waxy content the tubercle bacillus tends to form clumps when suspended, and as the agglutination and absorption of agglutinin test appears the most satisfactory method for the demonstration of "types" or "groups" in bacteria, it is obvious that this spontaneous agglutination presents a considerable obstacle to the carrying out of such tests. A recent observation is that by Smith, who investigated 11 strains of the human type of the tubercle bacillus. The suspensions used were made homogeneous by long shaking, and the immune sera were prepared by the inoculation of such suspensions into rabbits. He found that the strains fell into three groups, the first agglutinating to the full titre of the serum, the second agglutinating to partial titre, and the third showing no agglutination.

With bovine bacilli out of six strains examined four failed to agglutinate, while two agglutinated partially. No absorption of agglutinin test was employed. The strains used by Smith were mostly stock strains, and their origin was somewhat obscure. The number of strains examined was too small to permit of any definite conclusion being drawn from the results, but the indication was in the direction that "groups" did exist.

Attempts to Differentiate Groups.

An attempt to demonstrate "groups" has been recently conducted on a more extended scale by Tulloch, Munro, Ross, and Cumming. In this investigation 100 strains of tubercle bacilli were first isolated from cases of phthisis pulmonalis mostly in adults. The patients were resident in Glenlond Sanatorium, Fifeshire, which receives all stages of pulmonary phthisis in both sexes. At the time of isolation no particular attention was paid to the age of the patients, but it can be taken that the various age-groups were adequately represented. Seven of the strains were isolated from children under 13. Among adults, 50 strains were isolated from males and 43 from females. The age of the oldest adult from whom growth was obtained was 63 years. The series, therefore, were representative.

At the time of isolation it was impossible to test the pathogenicity of all of the strains, but 20 of them chosen at random were tested and all exhibited characteristic virulence for laboratory animals. The strains, with two possible exceptions, were all of the human type. These two were not completely bovine in characteristics, but were markedly dysgonic as compared with the remaining strains of the series. In this connexion it is of interest to note that Park and Krumwiede, in 592 strains of tubercle bacilli isolated from cases of pulmonary phthisis, only found one strain which seemed to be of the bovine type. They did not, however, accept it as a typical bovine strain.

The method adopted by Tulloch and his collaborators for the suspension of the bacilli was to extract with acetone and ether for four days in order to get rid of some of the fatty or waxy components, and then to grind up with a drop of 1.4 per cent. sodium bicarbonate, and finally, to suspend in 0.5 per cent. carbolic saline. Fleming and Douglas had previously shown that acetone extraction of the *B. typhosus* did not alter its antigenic qualities, and this observation was extended before proceeding to test the tubercle bacilli. It was shown that extraction by acetone and ether, in the case of *B. typhosus* and *B. paratyphosus* B, did not alter their antigenic qualities, nor did it interfere with their agglutination and absorption of agglutinin in the presence of specific anti-sera. The immune sera could be prepared equally well with a suspension of acetone and ether-extracted bacilli as with a suspension made in the ordinary way.

It was therefore postulated that there was no objection to the use of acetone and ether extraction in the case of the tubercle bacillus, and as the suspensions resulting from this technique were homogeneous and exhibited no tendency to auto-agglutination, all the bacilli examined were extracted and suspended in this manner.

The strains were tested by the agglutination and absorption of agglutinin test and the end-result was that of the 100 strains examined: (1) There was no member which failed to agglutinate in a dilution equal to at least half the titre of three-type anti-sera, by far the greater number agglutinating to full titre. (2) There was no one member which failed to absorb the agglutinins for the type bacilli from their respective homologous anti-sera. (3) The three-type strains employed were equally and mutually agglutinable by their anti-sera, which in turn were equally absorbable by the suspensions of the type bacilli.

Conclusions.

The conclusions drawn from these results are—that the tubercle bacilli isolated from 100 cases of pulmonary tuberculosis all conform to one well-defined serological type, and that while certain small variations do exist, these variations are negligible, being no greater than those found in other monotypical pathogenic micro-organisms. It would seem, therefore, that the statistical postulate of the existence of two groups of human tubercle bacilli still requires proof, and that the present bacteriological evidence is against the idea.

The second explanation advanced by Brownlee is one which has been more widely noted than the first, and some observers have claimed that it can account to a very large extent for the existence of the statistical types of the disease. Cummins has drawn attention to the relative frequency of tuberculosis in isolated and non-isolated communities. He shows that in the former tuberculosis is rare, due to a rarity of the tubercle bacillus, but that should an inhabitant from an isolated area enter an environment in which tuberculosis is common, he exhibits a greater susceptibility to the disease than the native inhabitants. Moreover, the disease in such a subject tends to be generalised, and rapid in its course. He considers that the immunity of the inhabitant of the "tuberculous" environment depends upon an active immunity which has developed as a result of contact with the bacillus from birth. At birth the infant is "virgin soil" and if, in infancy, infection with large doses of the bacillus takes place, the disease will develop in an acute and generalised type. If, however, the exposure is gradual and the infecting doses small, then a condition of active immunity is brought about which increases with every exposure to the bacillus, provided that the inoculation be not in overwhelming doses.

Cummins's explanation of the three types is coloured by his belief in this theory of infection and resistance. He considers that the "young adult" type, occurring as it does in the more isolated parts of the country, is intermediate in type between the "virgin soil" tuberculosis of isolated primitive communities and the "middle age" type occurring in communities where there is much intercommunication, and that the difference in environment and relative frequency of tubercle contamination determines the statistical type developing.

In view of the work of Tulloch and his collaborators the theory gains weight and would seem at present to be the most suited to explain the facts of the case.

Clinical and Laboratory Notes.

AN UNUSUAL CASE OF PENETRATING WOUND OF THE ABDOMEN.

By J. B. HANCE, O.B.E., M.B., B.C. CAMB.,
F.R.C.S. EDIN.,

MAJOR, I.M.S.; CIVIL SURGEON, DERA ISMAIL KHAN,
N.W.F. PROVINCE, INDIA.

CASES like the one under discussion, where a man lived for five months with a large arrow-head fixed in his abdomen after injury to important organs and recovered from the operation for its removal, must necessarily be infrequent.

The patient, a young Marwat Pathan of about 18 years of age, was admitted to the Civil Hospital, Dera Ismail Khan, on Oct. 27th, 1923, for abdominal pain, worse after food. The history of the case was that, five months previously, in the course of an intra-tribal feud, he had been shot in the eighth right intercostal space in the anterior axillary line with a steel-headed arrow. At the time he grasped the shaft and extracted it, and was carried to his village, where he remained for about four weeks ill. He could not remember if he ever spat up blood, but during this illness respiration was painful. After about four weeks he got up and went about as usual except for attacks of vague abdominal pain, which was aggravated by taking food. His attempts at dieting gave him transitory relief. A month previous to admission he noticed a swelling, which had been tender, in the left epigastric region. He then concluded that part of the arrow had remained behind, and consulted the nearest Government dispensary, whence he was referred to hospital, a journey of some 22 miles by camel.

Condition on Admission.—There was a reddened oval swelling about $1\frac{1}{2}$ in. by 1 in. in the left epigastric region, opposite the tip of the ninth left costal cartilage, and $\frac{3}{4}$ in. from the costal margin. This swelling was reddened and softened in the centre, but the patient stated that it was not nearly so tender as it had been before he started on his camel ride. He informed me that the feathered shaft of the arrow, complete, was in his possession, but that there was no trace of the steel head. He was put to bed preliminary to X ray examination next day.

During the night of Oct. 27th-28th, 1923, the patient "felt something move inside him," and next morning complained of a severe gnawing pain 1 in. below the left nipple. The patient was kindly skiagraphed for me by Captain H. H. Elliot, M.C., I.M.S. A black linear shadow was visible lying obliquely across the lower ribs. Operation had, unfortunately, to be postponed owing to a smart attack of malaria that evening with rigor and body pains, and on examination benign tertian parasites were found in the blood. Intensive quinine was given and operation postponed in the absence of acute indications. The pulse dropped to 72 with the sweating stage and remained down.

Operation.—Under chloroform anaesthesia an incision 5 in. long, best described in the words of Mr. R. P. Rowlands as a "left-sided Kocher's gall-bladder incision," was made, with the reddened swelling at its centre, and deepened at that point in order to localise any collection of pus that might exist. None, however, was found, the swelling consisting of partially organised granulation tissue, and the abdomen was opened along the length of the incision. On exploring with the hand, the arrow-head could be felt high up in the left hypochondrium pointing downwards, forwards, and to the right, moving markedly with respiration; and, on retraction, could be seen to be either intra-gastric or retro-gastric. The severe pain felt by the patient under the left nipple strongly suggested the former alternative, and the stomach was accordingly turned up and the gastro-colic omentum opened bloodlessly and the lesser sac investigated with the finger. It was then ascertained that the point of the arrow-head was firmly fixed in the posterior fibres of the diaphragm, and the lesser sac was obliterated round it, fairly firmly organised adhesions binding the stomach to the posterior abdominal wall.

The exact anatomy could not be made out, but Fig. 1 roughly represents the condition. It is to be supposed that the point of the fixation was in the neighbourhood of, but above, the left suprarenal capsule. It was thought to be advisable to leave the posterior gastric wall in this condition, and the lesser sac was accordingly closed with a catgut suture and the anterior cardiac end of the stomach drawn as

far as possible into the wound, fixed with Allis's forceps, packed off, and incised. The haft of the arrow-head was felt for, found in the fundus of the stomach, grasped with Mayo-Ochsner forceps and pulled out, and the stomach

FIG. 1.

Diagram to show position of arrow-head (A . . . B).

cavity investigated. Haemorrhage was fortunately negligible, and the anterior gastrotomy was closed with two layers of fine catgut sutures—through-and-through and Lembert—placed "in reverse." The abdomen was then closed, layer by layer, as recommended by Rowlands, and dressings having been applied, the patient was returned to bed.

The patient was kept on rectal feeds of glucose-soda bicarb. saline for 48 hours, after which peptonised milk was given for a further similar period, when diet was gradually but steadily increased till full diet was reached on the fourteenth day. Skin sutures were removed on the tenth day. The only incident of the convalescence was the necessity for catheterisation for 48 hours after the operation. This was largely temperamental, since the patient evinced marked objection to such novel (to him) experiences as the usual nursing measures. The difficulty, however, was definitely and finally solved by the injection of 1 c.cm. of pituitrin when the bladder was full. An hourly record of the pulse was maintained for 24 hours after operation, and the highest count, 96, was recorded on his return to bed from the operating-room.

Convalescence was uninterrupted, and the patient left hospital cured, and on full diet, on the twenty-first day after operation.

Commentary.

One hesitates to attempt to outline the course followed by the arrow-head, of which Fig. 2 is a

FIG. 2.

Arrow-head and shaft.

photograph, and of which the actual length is $6\frac{1}{2}$ inches. The position of the entrance wound and the situation in which the weapon was discovered would seem definitely to establish the injury of the following structures: (1) the right pleural cavity, (2) the right dome of the diaphragm, (3) the liver, and (4) the stomach, and it is the strongest possible commentary on the extraordinary vitality of the Frontier tribes that the patient came to the table at all; further commentary, if needed, being afforded by the uneventful convalescence.

My thanks are due to the assistant surgeon, Dr. Bhagwan Dass Dhamija, and to the staff of the Civil Hospital, already overworked, for their unremitting care and attention to this unusual case.

TWO UNUSUAL CASES IN SURGICAL PRACTICE.

BY LESTER SAMUELS, M.D. SHEFF.

THE following two cases—of fibro-lipoma of the kidney and irreducible hernia with colonic band—are, both from their comparative rarity in surgical history and their unusual symptoms, worthy of record:—

CASE 1. Fibro-lipoma of the Kidney.—This patient was a well-nourished married woman, aged 46. She was not neurasthenic; non-drinker. Symptoms: Pain left side of abdomen, two years, at times exceedingly severe with vomiting and semi-prostration; no hæmaturia. Frequency of micturition without pain during the severe attacks. Menstrual periods normal; urine normal; occasional severe occipital headaches. Examination: Heart, chest, and nervous system normal; retina normal. Fullness of left loin. Smooth tumour felt in left umbilical region, movable with respiration; tumour very tender to palpation. Urea-concentration test normal. Cystoscopic examination showed deficient flow from left ureter. X ray report: Dense patchy shadow left kidney; suggests hard growth. No calculus entire urinary tract. Right kidney normal.

Operation.—Lumbar incision. Opening into perirenal tissues a hard encapsuled mass presented. Kidney and descending colon pushed forward. Kidney normal in size and no abnormality found in substance. Incising tumour capsule a fatty mass quickly extruded and was easily removed. The capsule proved exceedingly difficult to remove, and was adherent to lower pole of kidney. Nephropexy was performed and wound closed with drainage. Recovery uneventful, with disappearance of symptoms. Pathological report: Tumour presents naked-eye and microscopical appearances of fibro-lipoma, benign in character.

Fibro-lipoma in this situation is of sufficient rarity to merit attention. The urinary symptoms were probably those of intermittent hydronephrosis.

CASE 2. Irreducible Hernia with Colonic Band.—The patient was a man, aged 50, with increasing pain and constipation; bowels moved about once in five days. Dyspeptic attacks. Double inguinal hernia. Examination: Large direct left inguinal hernia, irreducible. Some thickening felt over descending colon with tenderness on deep palpation. X ray report: Some obstruction, not complete in area of ileal and pelvic colon. May have some connexion with hernia.

Operation.—Incision as for radical cure of hernia. Lipoma surrounding cord structures. Cord structures separated and sac identified. Numerous adhesions between intestine and sac. Incision prolonged upwards, and peritoneum incised in line of sac incision. Fibrous band found encircling descending colon and constricting it to small finger opening. This band was about 1 inch thick, and continuous with the lipomatous tissue around the cord. Impossible to remove band around intestine, therefore excision of part involved and end-to-end anastomosis performed. Radical cure of hernia on both sides completed operation. Recovery uneventful.

The association of a lipoma of the cord and fibrous constriction of the bowel is not usual. The X ray report in this case was invaluable, otherwise the constricting band could easily have been missed with consequent non-amelioration of symptoms.

I have to thank Dr. A. H. Marsh of the Jewish Hospital for his accurate and helpful X ray work, Dr. Arthur Davies for his pathological reports, and my anæsthetist, Dr. V. R. Hirsch, for his assistance.

London, W.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF SURGERY, ANÆSTHETICS, MEDICINE, OBSTETRICS AND GYNÆCOLOGY, AND PATHOLOGY.

A MEETING of the combined Sections was held on Feb. 4th, Mr. HERBERT J. PATERSON, President of the Section of Surgery, being in the chair, when a discussion took place on the Prevention and Treatment of

POST-OPERATIVE PULMONARY AFFECTIONS.

Mr. E. C. LINDSAY (Section of Surgery) opened the discussion, and his paper appears in full in another part of this issue.

Dr. FRANCIS E. SHIPWAY (Section of Anæsthetics) said the two outstanding features of the two chief post-operative complications (bronchitis and pneumonia) were, first, their more frequent occurrence after abdominal (especially upper abdominal) operations than after operations elsewhere; secondly, their comparative rarity in private practice. Recognition of these facts would, he said, help to elucidate the problem of their ætiology, and therefore assist in their prevention. Bronchitis after operation might cause bursting of the wound, thus necessitating immediate operation, with its risk of sepsis, of aggravating the bronchial affection, and the formation of adhesions. Sometimes bronchitis arose, in mild degree, in a healthy patient after ether anæsthesia. It was caused partly by exposure, but was chiefly the result of loss of body heat.

Ether Impurities.

In some methylated ethers there were impurities, such as peroxides and aldehydes, which were increased on exposure of the ether to sunlight. Profound and prolonged ether anæsthesia was definitely harmful, particularly to certain types of patients, and, wherever possible, the concentration of the vapour should be materially diminished and relaxation obtained by the substitution of chloroform, or the employment of a local anæsthetic. Often spinal anæsthesia was very valuable for patients who were to be operated upon below the umbilicus. Dr. Shipway urged that the wonderfully good results obtained during the war from a combination of gas-oxygen and novocaine should not be forgotten. Excepting in hot weather, ether should be given warm. He considered that the ordinary hospital ward was too draughty, and could not be maintained at the optimum temperature for each patient.

Intratracheal Insufflation of Ether.

The speaker said he had used ether intratracheally in nearly 500 cases of facial, nasal, buccal, and pharyngeal operations, many of the patients having been of advanced years, and some of them chronic bronchitics, yet bronchitis seldom occurred after the operation on these, and pneumonia never. Hillman was favourably impressed by splanchnic analgesia, especially in cases for whom general anæsthesia was unsuitable. Expansion of the bases of the lungs by coughing or by breathing exercises was recommended.

Lord DAWSON favourably contrasted the giving of anæsthetics nowadays with that of former times, and said that, in his opinion, the anæsthetist was seldom or never responsible for post-operative complications, an exception being made, perhaps, in the case of the aged bronchitic, in whom only a slight irritant was necessary to determine an attack. Embolism was the most difficult and interesting of the complications, and Mr. Lindsay's figures were of high value. When a large clot became arrested at the bifurcation of the pulmonary artery, or at one of the larger branches, it might cause death instantly, or within a few minutes. When the clot was in a smaller artery the

area of infarction was usually limited by a patch of pleurisy, but many physical signs might be absent, and the diagnosis might have to be made on only vague evidences. He considered that small emboli were responsible for the attacks of slight pain and transient, irritable cough on the second or third, even to the eighth, day after operation. The larger the infarct, the greater was the danger of infection. Morphine was valuable not only in soothing the pain, but in rendering movement of the corresponding lung and chest possible. In his opinion the most common infecting organism was the pneumococcus, type 4, and that explained why so many of these cases recovered. Lord Dawson went on to discuss the *modus operandi* of emboli.

The Origin of Emboli.

Lord Dawson considered that thrombi form within the auricles of degenerated hearts, which had been enfeebled by operation or other cause; but he agreed that the majority of emboli in the lung originated in the systemic veins, the femoral and iliac being favourite vessels, mostly those on the left side. The accidents under discussion were those prone to occur in the second half of life, when the circulation was sluggish and the vessel walls deteriorated. Though trauma was so very common during the war, embolism of the lung was relatively infrequent, the subjects of these traumata being young and vigorous. Before thrombosis could occur he thought some activating agent in addition to sepsis must be operative. People with low blood pressure were specially apt to get thrombosis. The speaker thought the pneumonia in these cases was nearly always of the lobular type, and instances of this following operation were so few that they could not be regarded as anything more than accidents. The milder forms were probably unrecognised. Pneumonia might be the first indication that embolism had occurred. It was not always that the sputum was blood-stained following infarction.

With regard to infection, there should be a careful routine examination of the upper air passages before these abdominal operations. The influence of a common cold was well known. Following massive collapse there might be immobilisation of the diaphragm and interference with movement in the lower intercostal spaces, and this led to stagnation of the lung and impairment of the circulation of both air and blood, resulting sometimes in a blocking of the afferent bronchi and so also collapse. Massive collapse was usually recovered from, the symptoms disappearing long before the signs. It was a manifestation of exhaustion. Broncho-pneumonia could be much reduced by avoiding operation in non-urgent cases at times when influenza and lung troubles were rife, and by getting the upper air passages clean before the abdominal operation was undertaken.

The Obstetrical View.

Mr. J. PRESCOTT HEDLEY said that gynæcological operations had the unenviable reputation of being more commonly followed by fatal pulmonary embolism than any other kind of operations; but the records at St. Thomas's Hospital did not support this view. Wilson's figures at the Mayo Clinic gave ten fatal cases in 7993 gynæcological operations, or 0.12 per cent. In the same period 23 fatalities occurred in 12,229 operations on the gall-bladder, liver, prostate, colon, rectum, and for hernia—i.e., 0.18 per cent. In some cases, in which the pulmonary disturbance started with signs of bronchitis 12 to 36 hours after operation, the anæsthetic seemed to be the cause. If the patient had a common cold at the time of the operation the danger of complication seemed to be increased; possibly the anæsthetic stirred into activity a mild or latent infection. Emphysematous patients also were liable to these sequelæ. Not infrequently they occurred after local anæsthesia; in some, more examination under anæsthesia provoked them. Yet they were remarkably rare in accidental wounds and

fractures. The temperature of the operating theatre should not be below 70° F., and the patient should be protected from cold and draughts after the operation. Since the provision of tents over the conveying trolley, and curtains round the bed, there had been fewer cases of bronchitis following operation. Efforts should be made to prevent inhalation of vomit, mucus, or blood during the semi-conscious stage; there should also be careful handling of tissues. A patient whose circulation had become depleted by prolonged bleeding before operation, or by excessive bleeding at the operation, or who had been starved or purged, thereby had his liability to thrombosis increased.

Sir CHARLES GORDON-WATSON also referred to the danger of pulmonary complications after operations on the upper abdomen. During the war he saw many cases of severe abdominal wounds—especially wounds involving both abdomen and thorax—in which there was collapse, or inhibition, or paresis of the diaphragm. Dr. Pasteur's explanation was that an abdominal condition which was severe enough to cause reflex rigidity of abdominal muscles produced a relaxation of the diaphragm. In these cases, too, collapse of the base of the lung, especially the right, was very common, with blocking of bronchioles, stasis, and perhaps lobar pneumonia.

Prevention.

If severe operations on the abdomen could give 10·8 per cent. of pneumonia, prevention became a very important matter. There must be many accessory factors, of which irritation caused by the anæsthetic must be one, but Dr. H. W. Featherstone seemed able to show that it was not the important one. During the war Geoffrey Marshall's plan of warming the ether was followed by immediate good results. More recently the intratracheal method had further reduced the incidence of complications. Despite improvements in surgical technique, pulmonary embolism after operation was still a bugbear. At St. Bartholomew's Hospital three years before the war the surgical deaths from pulmonary embolism were 0·5 per cent.; for three years after the war they were 1·7 per cent.; and in the next two years the percentage rose to 2·9.

Causation.

Sir Charles Gordon-Watson considered that trauma and stasis were the two most important causative factors, but that there must be another to complete the process, possibly the absorption of thrombokinas, as had been suggested by Mr. Lockhart-Mummy. Factors in the production of the sluggish circulation which he discussed were: (1) purging, bleeding, sweating, and the withholding of adequate fluid after the operation; (2) lowering of blood pressure by trauma and the shock of prolonged operation, aided by morphia and continued immobility; (3) constrained posture during operation. He did not favour venesection, as he thought the patient could not spare the blood so withdrawn.

Dr. H. W. FEATHERSTONE said that if, as many believed, ether was an important factor in the production of the sequelæ under discussion, they should be more frequent after severe operations on the head and neck than they were. It had been found that ether, given by the intratracheal method, was particularly safe. He attributed great importance to the presence of an epidemic, such as of influenza, or ordinary colds in the causation of post-operative pulmonary conditions, and urged, therefore, that non-urgent abdominal operations should be deferred to times of comparative health among the main population.

Dr. ROBERT HUTCHISON remarked that more progress would be made in this matter if the cause of these complications was known. He considered that thrombosis which resulted in embolism was largely the result of the postural conditions required by the operation. The patient was placed into the position of a double-inclined plane, so that his body was really kinked, and the return of venous blood thereby inter-

fered with. This was aggravated by the fact that the operation, for the time being, practically paralysed abdominal respiration. He urged that the importance of chill after operation should not be overlooked; it was too much the custom to put insufficient clothing on to the chest after an operation, and to subject the enfeebled patient to direct draught from an open window.

Dr. W. J. MCCARDIE (Birmingham) agreed with Dr. Shipway and Dr. Featherstone in regard to the small part played by anæsthetics in these complications. He also contrasted the conditions surrounding private and hospital patients, to the great advantage of the former, especially in the matter of preliminary preparation and after-care. He advocated the establishment of recovery wards, specially staffed for cases which had undergone severe operations, on the plan adopted in Vienna. The responsibility in regard to the occurrence, prevention, and treatment of these complications rested, he considered, with the surgeon, not with the anæsthetist.

Dr. F. W. LONGHURST, also speaking as an anæsthetist, gave the result of his investigation of 700 consecutive operations at St. George's Hospital, and criticised the lack of efficient after-care of operation cases in hospitals. He considered various methods of anæsthetisation, and condemned ether by the open method because of the great amount of evaporation. Only ten cases of complication out of the 700 operations inquired into could be in any way attributed to the anæsthetic.

Dr. Z. MENNELL said he did not think the anæsthetist could be blamed in any way for the occurrence of pulmonary embolism, though perhaps some of the inflammatory effects following chest operations could be laid at his door. Ether he considered to have a more irritating effect than chloroform. A preliminary cold or infection predisposed to pneumonia after operation. It was found at St. Thomas's Hospital that a mixture of atropine, adrenalin, and strychnine definitely aided recovery from bronchitis or pneumonia.

Dr. C. F. HADFIELD referred regretfully to the too prevalent habit of making the anæsthetist the scapegoat when trouble occurred. Ether, he said, was not harmful to the healthy lung, and it would not harm patients if their alveolar secretion were reduced. It was the peroxides and aldehydes in some makes of ether which did the damage.

Sir CHARLTON BRISCOE said his own surprise was that so few patients had post-anæsthetic complications. He discussed the various unnatural conditions which were imposed by the operation on the patients, and showed how these favoured infection of the lower lobes of the lungs. An important pre-operation step was to see that the mouth was sound and clean.

Dr. G. H. BURFORD referred to the occurrence of glycosuria at the same time as these patients showed respiratory distress. The glycosuria usually cleared up some days before normality returned to the lungs.

Mr. J. E. ADAMS expressed his agreement with the points which Dr. Hutchison had put forward, and his approval of placing curtains round the beds of severe cases especially in the winter. He thought some of the patients were over-nursed, and especially too frequently washed.

Mr. LINDSAY briefly replied.

SECTIONS OF EPIDEMIOLOGY, COMPARATIVE MEDICINE, AND DISEASES OF CHILDREN.

A COMBINED meeting of these Sections was held on Feb. 9th, Prof. F. T. G. HOBDAV, President of the Section of Comparative Medicine, being in the chair. A discussion on the

CONTROL OF TUBERCULOSIS AND THE MILK-SUPPLY

was opened by Dr. J. ROBERTSON, who expressed the opinion that such a discussion was most opportune, particularly in view of the not inconsiderable difference of scientific and medical opinion as to the part played by bovine tuberculosis in the production of human

mortality and morbidity. On the one hand was the statement that 3000 children succumbed annually to a tuberculous infection of bovine origin, while tens of thousands suffered from other forms of bovine tuberculosis resulting in crippling and chronic ill-health; on the other hand, many experienced physicians stated that moderate invasion by bovine bacilli provided just that amount of immunity necessary to save the individual from infection with human tuberculosis, and that a few living bacilli in milk was a good thing for the preservation of the race. Dr. Robertson pointed out the close clinical and pathological parallel between the lesions and progress of the disease in cattle and man, and said that the same predisposing causes might undoubtedly be cited in both cases—viz., hereditary predisposition, bad housing, absence of light and air, poor food, exhausting conditions of life, &c. In his opinion the evidence available as to the amount of tuberculosis due to unhealthy milk-supply was sufficient to warrant public expenditure on the attempt to reduce the infectivity of milk. The three methods in use in Birmingham were the testing of milk samples taken in the city and the tracing and elimination of cows found to be yielding infected milk; the offer to farmers of free testing of their herds, provided they undertook to remove animals giving positive reactions; and the process of pasteurisation. During the last 18 years the percentage of churns sent into the city containing live tubercle bacilli had averaged 8·7, but the figure was decreasing. Microscopic examination alone was never relied on, the guinea-pig inoculation test being used; this resulted in a delay of two months, during which time the infected milk continued to enter the town. A small compensation for immediate slaughter had been paid by the city for many years before the Tuberculosis Order of the Board of Agriculture had come into force, and Dr. Robertson was certain that good had been done by the elimination of many wasting cows and in the education of the farmers, but the method as a whole was far too slow, and was expensive both in the time of the veterinary officer and in respect of travelling and laboratory expenses.

Bang's Method—Pasteurisation.

In 1906, as the result of a visit to Denmark, the isolation and testing methods of Prof. S. Bang had been introduced, and all cows were tested free twice in each year, and new additions to the herds at any time required. By this method a herd might be freed of tuberculosis in five years without any very serious expense to the farmer. The farmers had been willing to coöperate, as they anticipated from the periodic advice of the veterinary officers a reduction not only in the number of "wasters," but also in other cattle diseases and contagious abortion; 38 herds had by these means been freed, or nearly freed, by 1914, but the war had spoiled the best herds, and at the present time only 30 had been restored to pre-war level. In Dr. Robertson's experience the tuberculin tests gave as good results as any known form of test, when used by careful veterinary officers on ordinary dairy cattle housed quietly. On an average, 30 per cent. of the animals tested gave positive reactions.

In 1921 a visit to America to examine the results of pasteurisation in that country had convinced him of the value of this method if properly carried out, and at the present time from 60 to 70 per cent. of the milk retailed in Birmingham had been heated sufficiently to kill tubercle bacilli, and he hoped that soon no raw milk would be sold except from tested herds. Even then he would advocate the heating of milk for nursery use on account of the danger of contamination with scarlet fever, sore-throat, or other infection. In conclusion, he stated that he was in favour of the freeing of dairy herds from tuberculosis, but in view of the slowness and difficulties of this method and the need of many more veterinary officers, of much greater expenditure on cowsheds, and of prolonged education of agriculturists, he recommended adequate pasteurisation and bottling of all milk.

Lieut.-Colonel J. W. BRITTLEBANK pointed out that this battle must be waged, and its cost must fall in the domain of the agriculturist. Of the seven and a half million head of stock in Great Britain some three million were in milk, and of these at least one million were infected with tuberculosis, though in many cases so slightly that it did not affect their well-being, and indeed the encapsuled lesions were perhaps a protection to them. In Manchester 10 per cent. of the milk samples taken in the city showed living tubercle bacilli, and, unlike Birmingham, the proportion had increased since 1901. Nevertheless, farm inspection had revealed tuberculosis of the udder in 597 cows during that period, and these were mostly animals producing plenty of milk and in the middle of their active period, so that some good must have been done by the elimination of that amount of infection. But the piecemeal measures so far adopted had done nothing to reduce the incidence of bovine tuberculosis; they could be but preliminary to the introduction of future adequate legislation. Their danger lay in the lulling of some portion of the health service into a false security. Dairy farmers as a class were unable to appreciate the value of preventive medicine and were liable to regard any progressive measure with suspicion, and it was hard to convince them of their error so long as it remained a fact that the public would buy the cheapest milk on the market; and the more so in that the earliest animals to react to tuberculin were those producing the greatest quantity of milk, which were of the greatest value for breeding. The isolation measures proposed by Bang were not feasible on a wholesale scale except in specially selected herds, and freedom from disease could only be secured where there was indefatigable industry, ceaseless vigilance, ample accommodation, and plenty of money. Colonel Brittlebank described the breeding of a model herd before the war; it had been found that the introduction of animals from outside, even though they were tested on entry, had resulted in infection; the herd had therefore been made self-contained, and of the 257 calves reared not one showed any tuberculosis, and the average output per cow per annum had been raised by some two or three hundred gallons. The pneumonia incidence was considerably lowered, and there was no contagious abortion. After 1915 no veterinary advice had been obtainable, and although the farmer had attempted to carry on the testing himself an infected cow entered the herd and by 1916 37·5 per cent. reacted positively to tuberculin, demonstrating the remarkably rapid spread in unprotected animals. At the present time Manchester relied on clinical examination of herds and testing of mixed samples. Colonel Brittlebank gave some interesting figures illustrating the conditions in farms visited by him in 1909. Of 136 farms seen, 6 were clean and 52 fairly clean, the others being frankly dirty, even judged on a moderate cowshed standard, and in summer. Five only had any sort of provision for manure storage. Of 346 sheds inspected, only 10 were clean, and in 78 the lighting, in 88 the ventilation, was satisfactory. Eleven cows out of 3019 had tuberculous udders. Watching the local markets, Colonel Brittlebank noted that wasters were being sold in large numbers for sums ranging from 10s. to 35s., and of the 17 cows he saw sold in one market 14 had advanced tuberculosis, in nine cases of the udder. He had revisited these farms in 1925, and found that they were all in precisely the same condition as at his previous visit. He felt that there was little hope of being able to proceed to the wholesale elimination of bovine tuberculosis so long as such conditions remained; there was a colossal task before us in this respect, though the work was well worth doing and would result in most valuable results both to public health and to agriculture. He recommended that the Tuberculosis Order should be so amended as to require the inspection of every dairy farm in the country without waiting for the notification of obvious tuberculosis; that compensation should not be offered for decrepit and emaciated animals, but that rather it should be a disgrace for such a beast to be kept on

any farm; that meanwhile pasteurisation should be extensively practised, although it had certain disadvantages and was not a panacea, and however good the pasteurisation plant might be it was still essential that all dairy herds should be examined and that the sources of supply should be only such as would give a reasonably clean milk.

Prof. S. L. CUMMINS emphasised the paramount importance of the very difficult question as to the danger or possible value of living tubercle bacilli in milk, and urged the necessity of consolidation of opinion between medical men and veterinary officers with a view to formulating a definite policy to lay before the public. He had been much impressed by Colonel Brittlebank's example of the dangerous position of a tuberculous-free herd unless the extraordinary protective measures could be maintained indefinitely, and pointed out that in places, such as large tracts of Africa and India, where bovine tuberculosis did not occur, the human form, if it appeared, was of a far more virulent type than elsewhere.

The Quantitative Element.

He urged a consideration of the quantitative element in the problem, it being undoubtedly true that the presence of bacilli in sufficient dilution produced no clinical infection. In the production of an adequate dilution the process of pasteurisation was undoubtedly important, however much it might be impugned theoretically as leaving a certain number of bacilli alive in some cases; also of importance was the mixing of milk in cities. A far more intense danger of infection arose in country districts where a child might be fed on milk from one or a few cows on the home farm only. Another point in this connexion was the lack of consistency between the attitudes towards human and bovine milk. Doctors advised mothers to feed their babies provided there was no active clinical tuberculosis, in spite of the fact that something like 80 per cent. of human beings gave a positive tuberculin reaction. The cow was submitted to a far higher standard, but of course the cow was living in an extremely artificial state, and it was possible that that influenced the infectivity of the milk; perhaps also the handling of the udder might tend to activate lesions otherwise quiescent. Prof. Cummins maintained that the death of a guinea-pig as a result of inoculation of the centrifuged deposit of a large quantity of milk could not necessarily mean that a diet of that milk would be fatal to a child. As a poor country we could not at present attempt the complete extirpation of tuberculosis in cattle; we must deal with the practical problem of elimination of dangerous infection first.

Dr. J. NIVEN described the methods employed in Manchester since his appointment in 1894—viz., the distribution in three successive years of handbills advising the boiling of all milk, a record of the conditions in all farms supplying milk to the city and immediate suppression of unsuitable sources of supply, instruction of health visitors and school-girls in the preparation and keeping of milk for infants, the appointment of a veterinary inspecting officer, testing of samples of mixed milk, visitation of farmers, and education of agriculturists and consumers. He then referred to Dr. Robertson's report on the milk control in America, the success of which he attributed to the extensive powers of local authorities independent of the central governments. Any small town could exclude from its shops the milk of a dirty dairy, all retailers had to have a permit, which would be rescinded if they were found selling adulterated milk; this term included milk from any cows fed on distillery waste or unwholesome food and from cows living in crowded or unhealthy conditions. The inspectors had power to seize, test, and destroy the milk of any retailer at any time without compensation. Dr. Niven urged the insistence on sterilised milking pails of good pattern, of the clipping, washing, and drying of the udders, of not leaning against the cow whilst milking, of special milking sheds, shavings

rather than straw for bedding, dusting of floors with powdered quicklime, and proper washing of the bodies of the animals. He considered that the leeway in this matter in our country could be made up if the recommendations of the Astor Committee were followed, though a difficulty here was the inadequate supply of ice. He did not consider that we were ready for a system of compulsory grading at present. He considered that all local authorities should have power to carry out adequate inspection of the sources of supply, combined with instruction by the veterinary inspector.

The discussion was adjourned until March 2nd.

SECTION OF OTOTOLOGY.

A MEETING of this Section was held on Feb. 7th, Dr. KERR LOVE, the President, being in the chair.

Mr. G. J. JENKINS read a paper on

Septicæmia and Acute Middle-ear Infections.

He said that in his experience the septicæmic state was more common in middle-ear infection than in any single intracranial complication. There was a danger that middle-ear infection in early septicæmia might not be recognised. The septicæmic state was much more likely to be met with in children than in adults, and perhaps mostly in those who had not previously had a gross lesion of the ear. When the incidence of the septicæmia occurred in the early stages of infection of the middle-ear tract there might be no obvious local inflammatory signs. If the septicæmia came on at a later stage of inflammation the appearances presented were those of chronic suppurative middle-ear disease. In some cases the septicæmic state so masked the local signs that even the skilled otologist might find it difficult to recognise the serious local lesion, so that it was not surprising that it was sometimes missed in general practice. A sudden cessation of pain and discharge, with an obvious alteration in the patient's general condition, should send the doctor to a careful examination of the ears. A "laking" of pus in the big cells, a thin, pale mucous membrane, and absence of congestion were characteristics of the mastoiditis preceding the septicæmic state. Mr. Jenkins stressed the importance of thoroughly dealing with the middle-ear condition, a Schwartze operation and paracentesis being generally needed. With regard to the treatment of the general infection, until recently it had been his custom to give these patients large doses of normal horse serum as soon as that was possible, continuing this as long as needed; but recently he had employed immuno-transfusion, and, so far, he was favourably impressed by it. He had not been successful with vaccine-therapy in these cases. Severe cases were of much more rapid development than the milder ones, and treatment appeared to have on them little or no effect.

In the discussion which followed, Mr. SYDNEY SCOTT, Dr. W. T. GARDINER, Dr. NEIL MACLAY, Mr. A. R. TWEEDIE, and Dr. W. S. SYME took part.

Anastomosis of Facial Nerve in Facial Palsy.

Mr. LIONEL COLLEDGE and Dr. L. D. BAILEY gave a cinematograph demonstration of results of three operations for anastomosing the facial nerve after the occurrence of facial palsy. The actual behaviour of the various facial muscles on stimulation at various stages were well depicted by this means, and the question was discussed by Sir CHARLES BALLANCE, Dr. SYME, Mr. SYDNEY SCOTT, Mr. JENKINS, and Dr. A. A. GRAY.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society will be held at the Miller General Hospital, Greenwich, S.E., to-day, Friday, Feb. 13th, at 8.45 p.m., the President, Dr. H. S. Knight, in the chair, when Dr. Harold Pritchard will read a paper on Some Modern Aspects of Disease.

MEDICAL SOCIETY OF LONDON.

THE TREATMENT OF LYMPHADENOMA.

AT a meeting of this Society on Feb. 9th, with Dr. E. M. CALLENDER, the President, in the chair, a discussion took place on the treatment of lymphadenoma.

Sir THOMAS HORDER, in opening, said that his request to report to the Society two cases of the Pel-Epstein or relapsing pyrexial type of lymphadenoma, in which a certain treatment was followed by much better results than had hitherto been recorded, was met by a suggestion that he should open a discussion on the general subject of the treatment of the disease, and to this he readily agreed. He first described the two cases, both of them men between 40 and 50 years of age, in which there was a periodical rise of temperature of such a nature that, in one case at any rate, it was regarded initially as influenza. In the first case he gave the history in detail and showed the temperature charts. In June, 1922, other treatment having produced no results so far as the pyrexial condition was concerned, he decided on an intensive course of arsenical treatment by intravenous injection, coupled with X rays applied to the liver area, the first application of X rays being made a few days after the completion of the arsenical injections. This treatment upset the rhythm, hitherto constant, of these recurring attacks, but improvement was not maintained, and in October he (with Dr. Knox on the radio-therapeutic side) determined to proceed a second time with neokhar-sivan and X rays, but with closer synchronism than was observed in the first instance. An attack which was ordinarily due in November was aborted, and although there was an isolated attack in January, 1923, there had been no other recurrence up to the time the patient was last heard of (midsummer, 1924). The treatment had been continued until the end of March, 1923, the X ray applications being given every second day during the course of arsenical injections. In the second case, the patient, who was very ill indeed, was subjected to the same treatment, with the same result. As to which of the two agents employed—neokhar-sivan given intensively and intravenously and the X rays—was of the more value therapeutically, his own impression was in favour of the X rays, but it might be that the combination was desirable even if not essential. It was also his experience that to synchronise rather than to separate these two measures was the more effective procedure. In the arsenical dosage one must be a little courageous, but he could lay down no hard and fast lines; the individual case must be the guide. In the first of his cases he had no proof, either from what was seen at a laparotomy or from physical signs, that the liver was badly hit, the patient was never jaundiced, and was well between the periodical attacks, so that although he thought the lymphoid tissue of the liver was the avenue of infection, he was prepared to "bank" on a good deal of hepatic sufficiency and to give the neokhar-sivan in fairly liberal doses. So far as the dosage of X rays was concerned, he would leave that to Dr. Knox. He had had no experience of radium in this type of case, but radium had been used in cases of localised glandular or nodal lymphadenoma which had come under his observation. One case in particular was that of a boy, 7 or 8 years of age, who had abdominal lymphadenoma, with recurring ascites and large masses of glands. This boy took arsenic by the mouth very badly, and was treated at the Radium Institute with very striking results. He had also had some recent experience of one of those very interesting but rare cases of lymphadenomatous disease of the spinal cord. Here an attempt was made to synchronise the intravenous injection of arsenic with radio-active measures; with X rays very little result was forthcoming, but with radium the improvement was surprising, and the patient, who had not previously been able to walk

at all, was now able to get about with a stick. With regard to other treatments, he wondered whether anyone had tried any other drug than arsenic—antimony or bismuth, for instance—or any other route than the intravenous. Had anyone succeeded with protein shock in altering the course of one of these more generalised types of lymphadenoma? Surgery was of recognised value, but must necessarily be limited to those cases in which groups of glands were enlarged with as yet no sign of the general lymphatic tissue being involved. Cases with which he had been faced several times lately presented a special problem—cases which, although the glands had been got rid of, and the liver and spleen showed no signs of disease, were cachectic and showed progressive loss of weight and strength, with an obviously bad blood picture. These cases appeared to be more common than formerly; probably the truth was that, the early stages being more amenable to treatment, medical men were made aware of them more frequently. He did not think that arsenic would be of any use in such cases, and X ray treatment was probably contra-indicated. The thing to do would be to put these patients out into the sun and to try to enable them to recover their general resistance.

Dr. ROBERT KNOX said that in response to radiation treatment lymphadenoma gave sometimes an extraordinary result—a rapid disappearance under appropriate dosage, a period of usual health, extending sometimes to many years, followed by recurrences, in some cases amenable to further treatment, but in the end in all cases defying it. Next to the simple inflammatory tumour, lymphadenoma gave the best response to radiation treatment. The treatment must be systematic, and there were differences of opinion with regard to the particular type of radiation which should be employed. X rays gave a marked response in glandular and mediastinal conditions, while for the manifestation of the disease in the deeper regions, and particularly in relation to bones, radium appeared to give rather better results. The dosage with either agent need not be excessive, preferably small doses at short intervals of time, extended over a long period. In cases which had responded favourably and apparently had cleared up the treatment had been stopped; this in his opinion was a mistake. Having established a degree of control over the morbid condition it should be their object to maintain that influence by giving at regular intervals a moderate dose. The nature of the control exercised by radiations was somewhat difficult to understand; in all probability the influence was exercised through the blood-stream, and in treatment by radiation certain biological processes were modified and directed towards a more normal course. He favoured the use of combined treatments. In the acute cases rest in bed, fresh air, sunlight and its artificial equivalents, arsenical preparations, were all useful. The employment of X rays and radium to the internal organs of the body might be regarded as an extension of surface light treatment, and the action might be the same in both. No case should be treated by the radiologist before he had discussed it fully with the clinician. The day had gone by when one could say, "Here is a case of lymphadenoma, let us treat it with X rays." All factors must be considered, and a definite scheme of dosage evolved. It was useless to pretend that it was exactly known what happened when combined measures were used, but he felt convinced that in the present method of attack they were proceeding in harmony with the fundamental principles of radiation therapy, and that such work as had been referred to by Sir Thomas Horder would lead a long way on the road to a complete understanding of what actually took place when radiations were used. That a degree of control could be exercised in a number of diseases there was no doubt. If in the end they were enabled to understand the rationale of radiation therapy it might only be a short further step to appreciate the disordered functioning of the living cell which constituted disease as at present understood.

Dr. PARKES WEBER said that he took it that lymphadenoma was what was mostly called Hodgkin's disease in England. This disease had a definite pathological anatomy. One of the essential points was the presence of the so-called Hodgkin's disease giant cells. The general opinion in America, Germany, Austria, and, he thought, also in England, was that in all probability Hodgkin's disease, as it was called here, was not a variety of tuberculosis, but a disease of unknown origin—that is, unless some suggestions put forward in America as to a specific bacillus turned out after all to be correct. He believed that precise diagnosis was essential. The enlargement of cervical or axillary lymph glands might be more or less imitated, not only by tuberculosis and syphilis, but also by various tumours. A chronic swelling on one side of the neck in a young woman, which he had at first thought was of the nature of Hodgkin's disease, turned out, on exploratory biopsy, to have the structure of adenocarcinoma. He did not understand that any biopsy was made in the two cases brought forward by Sir Thomas Horder. He found it difficult to accept both cases as true examples of the condition stated, although they were none the less valuable because of the wonderful results of the treatment, which, after all, from the patient's point of view, was the great thing, and they would give a great stimulus in the treatment of cases which resembled this Pel-Epstein type of fever. He also wished to ask the X ray specialists whether, in treating cases which were apparently those of Hodgkin's disease, they did not think that sometimes their treatment did harm—that although they brought about a rapid diminution of a group of glands on one side of the neck, they set up other disturbances. For his own part he had a suspicion that X ray treatment did sometimes hasten death in these cases.

Dr. A. SALUSBURY MACNALTJ said that his own experience of the treatment of lymphadenoma had been restricted chiefly to cases of the disease with relapsing pyrexia. The most beneficial results had been obtained with arsenic. As Dreschfeld found, this drug not only benefited the general health of the patient, but in two of his (the speaker's) cases it caused a diminution in size of the enlarged lymphatic glands and abolished the pyrexia. He proceeded to describe the two cases, but added that, unfortunately, both of them had been lost sight of and could not be traced. Treatment by salvarsan or its substitutes had proved disappointing in several instances. In cases of chronic lymphadenoma application of the X rays or of radium might cause the affected external glands to diminish, but, in his experience, neither treatment had a permanent beneficial effect on the form with relapsing pyrexia. One patient in his series first came under observation as a case of chronic lymphadenoma. Under X rays the enlarged external glands entirely disappeared. Soon afterwards he developed lymphadenoma with relapsing pyrexia and enlargement of the internal lymphatic glands. A troublesome dermatitis not infrequently ensued in cases exposed to X rays and compelled the discontinuance of the treatment. Operative treatment was indicated only as a palliative measure to relieve pressure by the enlarged glands on the trachea. In a case reported by Dr. Batty Shaw a certain number of lymphadenomatous glands in the neck were removed. Surgical treatment proved no safeguard to the onset of the acute form of the disease.

Dr. DOUGLAS WEBSTER referred to the great importance of diagnosis. He had had about 40 cases of this condition within the last few years, and several of them had later turned out to be tuberculous. Tubercle followed lymphadenoma like a shadow. Undoubtedly several of the patients he was at present treating had both lymphadenoma and tubercle. He fully subscribed to the view emphasised by Dr. Knox with regard to the need for collaboration between the radiologist and physician. One interesting point was as to whether X rays or radium had the better

effect. In this connexion he related the case of a patient who was treated on one side of the neck with X rays and on the other side with radium. Radium proved to have the quicker effect, but the side treated by radium recurred sooner.

Mr. WARREN LOW remarked that, some years ago, he operated on glands which were regarded as lymphadenomatous, but which the pathologist afterwards demonstrated to be both lymphadenomatous and tuberculous. Until then he had not realised that the two things might coexist.

Sir THOMAS HORDER, replying to Dr. Parkes Weber, said he was a little surprised that there should be any doubt as to the nature of his two cases. He was not dealing with Hodgkin's disease. Hodgkin could not in the nature of things have suspected what was the matter with his two cases. Nor could he have made such an apotheosis of biopsy as Dr. Parkes Weber, because biopsy was then unknown. Dr. Parkes Weber left out of account the observation that when these cases died—as they always did until these particular patients put up some resistance—the liver was found to be almost indistinguishable from the liver in a fatal case of Hodgkin's disease. He felt that he had been justified in bringing before the Society two cases of lymphadenoma of a particular type, seeing that the results of treatment in these cases must certainly be of value, as they threw light on the treatment of the common type of Hodgkin's disease which was so much more frequent and so much more likely to come under the observation both of the physician and of the radiologist. His own feeling was that the key to the treatment of the common case might often be found in the treatment of the uncommon.

GLASGOW ROYAL MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on Jan. 26th, Mr. JOHN PATRICK, the Vice-President, being in the chair, when a discussion took place on

TETANY.

Prof. LEONARD FINDLAY, in introducing the discussion, recalled briefly some of the outstanding events in the history of the disease. Although convulsions during the dentition period had been known to Hippocrates and Galen, it was only at the beginning of last century that tetany was first appreciated as a distinct entity, when Clarke, in 1815, devoted a chapter of his book "Commentaries on Some of the Most Important Diseases of Children" to "a peculiar species of convulsion in infant children." In 1860 Trousseau once more described the three signs of carpopedal spasm, laryngismus stridulus, and convulsions as manifestations of one disease. In 1874 Erb described the increased electrical excitability, and in 1876 Chvostek noted the increased mechanical excitability of the peripheral nerves, both of which phenomena were of great value in detecting the latent stage of the disease. Prof. Findlay then referred to the various hypotheses as to the pathogenesis of the disease and to the relationship of idiopathic tetany to tetania parathyreopriva and concluded by describing the investigations of Prof. Noël Paton and himself, which had led them to the adoption of the guanidin intoxication hypothesis.

Dr. STANLEY GRAHAM then discussed briefly the main theories regarding the aetiology of tetany as suggested by various workers from a study of the blood chemistry. The four main hypotheses held at present were (1) guanidin intoxication; (2) a disturbance of the ratio of sodium and potassium to calcium and magnesium; (3) calcium deficiency; and (4) alkalosis. With regard to the guanidin intoxication hypothesis he was of the opinion that until more accurate methods for the estimation of guanidin

were devised little further confirmation could be obtained. The action of sodium and potassium as irritative salts and of calcium and magnesium as sedative salts had been known for many years, and it had been suggested by several workers that a relative increase of the irritative or decrease of the sedative salts in the blood would account for the increase in the excitability of muscle. He considered that, though theoretically such disturbance of the ratio could be responsible for an increase in electrical excitability of the muscle, it seemed to play very little part, if any, in the production of tetany as seen clinically. The association of a diminished calcium content in the serum with certain forms of tetany he had found to be by no means constant, and in two recent cases of active tetany the calcium content had been normal. Also in other forms of tetany—gastric and hyperpnoëic—the calcium content might be normal. In uræmia with a low calcium content no instance of tetany had been recorded. The disappearance of the signs of tetany on the administration of calcium chloride, supposed to be due to the supply of calcium-ions, was now considered to be due to the acidosis produced. Ammonium chloride had been found to be as effective as the calcium salt, while calcium lactate failed to relieve the tetany. The acidosis of a gastro-enteritis had been found to cause the signs of tetany to disappear. Dr. Graham concluded by discussing the alkalosis hypothesis in its relation to the various types of tetany, and showed that while it was greatly concerned as a factor in all the types of tetany it was unlikely to be the causative factor. A toxic factor in the presence of an alkalosis might account for many of the symptoms, but such hypotheses at present lacked substantial confirmation, and the part played by the phosphorus was also deserving of further investigation.

In the unavoidable absence of Dr. GRACE H. ANDERSON, Prof. FINDLAY read her contribution on the treatment of infantile tetany. Some of the earlier methods of treatment were first described and the reasons for their failure discussed. Dr. Anderson then went on to describe the mode of administration of calcium chloride adopted by her. In the active stage with the three cardinal symptoms present it was best to give the drug in 30 gr. doses every four hours till all symptoms had disappeared. It was found that the urgent symptoms disappeared after one or two doses, but the latent signs took two or three days to vanish. In the latent stage of the disease smaller doses could be given and continued over a longer period. The drug was well tolerated by infants, though the disagreeable taste made the tabloid form preferable in older children. Dr. Anderson concluded by referring to the treatment of tetany by ultra-violet radiation, of which, however, she had no personal experience.

In the discussion which followed, Dr. G. H. CLARK concurred in the view that some form of intoxication was responsible for tetany with probably an alkalosis as an important or even determining factor. He found it difficult, however, to agree with Prof. Findlay in blaming the parathyroid gland for idiopathic tetany and believed the cause to be gastro-intestinal. He thought it unlikely that a disease showing practically the same symptoms in adults and in children should have a parathyroid origin in the latter and not in the former, and no one would suggest that parathyroid disease was the cause of tetany in cases of dilated stomach, cholera, or enteric fever, for example. Diseases of endocrine origin were with a few exceptions uncommon and not readily amenable to treatment, whereas idiopathic tetany was by no means uncommon and was fairly readily treated. Dr. Clark then referred to a case already described by him and considered to be a case of true parathyroid disease which had yielded to the administration of dried parathyroid extract.

Dr. J. ADAM spoke of the experience gained in treating a large number of cases of laryngismus stridulus. He likened this condition to an asthma of the larynx

and spoke of the toxæmic factor associated with asthma. He had found also in spasmophilic children an eosinophilia similar to what was found in toxæmia. He referred also to the importance of diet in the treatment, and to the part played by carbohydrate excess.

Dr. GRAHAM and Prof. FINDLAY replied briefly to the various points raised in the discussion.

Clinical Cases.

Dr. JAMES R. RIDDELL described briefly a series of five cases of *malignant disease of the throat and mouth* which had been treated by deep X ray therapy.

1. Epithelioma of the lower jaw and gum—confirmed by pathological report—treated with three doses of X rays by the Erlangen method over a period of five months. No recurrence since healing took place 18 months ago.
2. Tumour of left vocal cord, clinically malignant, treated by two doses—has remained well for 20 months.
3. Ulcerating tumour in region of left vocal cord and anterior commissure involving the subglottic region. Treatment commenced in August, 1924, and has been followed by complete disappearance of the tumour and restoration of function and marked improvement in general health.
4. Alveolar carcinoma of left tonsil and soft palate and gum. Treated by three doses of deep therapy. Showed an apparent cure, but recurrence followed on the hard palate within a fortnight for which radium was used. Patient has remained well for one year.
5. Sarcoma of right maxilla—confirmed by pathological report—treated by both radium and deep therapy. Patient has been well for six months. Two of the patients were shown to the Society.

Discussion.

In the discussion which followed, Dr. J. L. HOWIE remarked that he had found the results of the Erlangen method somewhat inconstant—some did well and others did not, and was of the opinion that the treatment should be commenced as early as possible. Some of his patients had complained of thirst after the treatment, owing probably to interference with the salivary glands.

Dr. ADAM considered that the results with the Erlangen method would be much improved when the control of the dosage could be more accurately determined. He had had some very good results in sarcoma of the mediastinum. In malignant disease of mucous membrane radium gave excellent results at first but recurrence was common. He had found radium more effective in sarcoma.

Prof. J. H. TEACHER inquired as to the extent of the reaction produced by the method.—Mr. PATRICK referred to the difficulties of operative interference after deep therapy from the presence of a very hard tough slough and from the slowness of healing afterwards.

Dr. RIDDELL replied to the various points raised, and emphasised the importance of regulation of the dosage, with a view to the avoidance of delayed necrosis, which had been noted in some cases as long as 18 months after treatment had ceased.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The sixteenth meeting of the Royal Commission on National Health Insurance was held at the Home Office, Whitehall, on Feb. 5th, Lord Lawrence of Kingsgate in the chair. The main part of the sitting was devoted to the examination of Mr. F. W. Daniels, chairman, and Mr. P. Rockliff, secretary, of the Joint Committee of Approved Societies. The subjects dealt with included the scope and quality of medical benefit, the possibility of limiting cash benefits so as to leave more funds available for treatment benefits, the benefits of married women, the pooling of surpluses. Thereafter, Mr. E. E. England, representing the Stock Exchange Clerks Approved Society and the Baltic and Corn Exchange Society, and Commander E. G. Holdway, representing the Lloyds Health Insurance Society, were examined on a variety of matters relative to these societies. The Commission announce that proof copies of the oral evidence and the relative statements submitted at the meeting of Jan. 22nd are now on sale at H.M. Stationery Office, Adastral House, Kingsway, London, W.C.2, from which they may be obtained on remittance of cost (2s. 3d.) and postage.

Reviews and Notices of Books.

ALLEN'S COMMERCIAL ORGANIC ANALYSIS.

Fifth edition. Vols. I. and II. Edited by S. S. Sadtler, S.B., E. C. Lathrop, Ph.D., and C. A. Mitchell, M.A. London: J. and A. Churchill. 1924. Pp. 796 and 807. 30s. for each volume.

DURING the ten years which have elapsed since the fourth edition of this well-known work was published organic analysis has made rapid strides, and this progress is reflected in the volumes under review. Each of the contributors to the different sections is an authority on the subject upon which he writes. The arrangement is the same as in former editions; there is, however, evidence of a closer collaboration between the English and American authors.

From much of the elementary subject-matter contained in the introduction one might assume that the book is mainly suitable for students; but "Allen" has long been recognised as perhaps one of the most valuable English handbooks available for the use of the practising analytical chemist. While many other instruments employed in analytical work are described in detail, no account is given of the microscope. The subjects dealt with in this volume include the alcohols and alcoholic beverages, yeast, alcohol derivatives (ether, chloroform, formaldehyde, chloral, &c.), sugars, starch, paper, and the aliphatic acids, and under these headings will be found many substances of therapeutic value with their methods of preparation briefly described; physical and chemical properties, methods of detection and estimation, together with tests acting as criteria of purity are given in all cases. The methods of analysis described, whether official or otherwise, are given with full details of manipulation. Little fault is to be found with the subject-matter, although it is difficult to understand why various forms of apparatus for the physical testing of paper are included in a volume on organic analysis. Again, the reader who turns to the eight pages on urine analysis will be disappointed to find that these deal only with the detection and estimation of sugars in urine, other constituents being referred to elsewhere under different headings.

The volume falls below the level of its predecessors only in so far as a number of minor blemishes are to be found. Some of the references both in the text and also in the index are incorrectly paged, misspelt words are by no means uncommon, and the page-headings in some cases have no connexion with the subject-matter beneath; whilst many items of more or less importance are missing from the index. A volume of such undoubted merit is worthy of more care in the proof-reading and indexing. The general reliability of the volume maintains the high standard of former issues.

Vol. II. deals with fixed oils, fats, and waxes, and the methods of analysis of butter, fat, lard, linseed oil, higher fatty acids, soap, glycerine, wool-fats, cloth oils, and sterol alcohols. That portion of the work dealing with the general properties and analytical methods is contributed by Mr. C. A. Mitchell, the English editor of this new edition, and it constitutes nearly one-half of this volume. It is a valuable monograph and an unusual amount of care has been taken in its compilation. An interesting section on butter-fat and its analysis is revised by Mr. E. R. Bolton. The use of hardened or semi-hardened fats has complicated indeed the analysis of margarine mixtures, for, as is well known, the process of hydrogenation destroys the identity of the original fat or oil except so far as the saponification value may serve, and if the process be carried to any great extent the liquid vegetable oils begin to assume the properties of the solid fats. One of the American editors, Dr. E. C. Lathrop, writes on soaps and their methods of analysis. This

and the following section on glycerol by Dr. T. W. Lawrie are interesting alike to the general reader and the specialist. That somewhat complicated class of bodies known as the sterols are lucidly dealt with by Mr. J. A. Gardiner; the description of and the separation of these bodies from tissues and their chemical examination will be appreciated by physiologists and biochemists.

A perusal of this volume conveys the impression that the work has been more carefully prepared and better edited than Vol. I. Although it is intended primarily for laboratory use, there are many parts of it which will be of the greatest use to those who are concerned with the chemical side of medical science.

AN INTRODUCTION TO DERMATOLOGY.

Eighth edition. By Sir NORMAN WALKER. Edinburgh: W. Green and Son, Ltd. 1925. Pp. 273. 20s.

A NEW edition of this work is always awaited with interest by English-speaking dermatologists, for, in spite of his engrossing activities in other fields, Sir Norman Walker contrives not only to keep himself informed of new lines of investigation and treatment in dermatology, but also to test them for himself. His verdicts thus command respect, even if they do not always meet with general agreement. The convenient size of the book—and to convey so much information in less than 300 by no means closely-printed pages is a remarkable achievement, the charm of the writing, the practical "tips," and the many beautiful illustrations, of which 92 are coloured plates, make this volume an admirable introduction to dermatology.

It is worthy of note that Sir Norman Walker, whose experience in the treatment of lupus vulgaris is admittedly very large, states that under no other method of treatment has he seen such rapid and satisfactory improvement as in under treatment by one or other of the "Sunshine" lamps. Even quicker and better results are obtainable with actual heliotherapy in places where the amount of sunshine admits of more or less continuous treatment. The value of heliotherapy or artificial light-baths in infections other than tuberculosis—e.g., chronic staphylococcal and streptococcal infection—is not yet sufficiently appreciated either in this country or abroad. It is curious that Sir Norman Walker still clings to what may be called two dermatological heresies, one that psoriasis is the "extremely dry form of seborrhœa," the other that alopecia areata is due to an external infection and is contagious. As Civatte has insisted in a recent paper, the histological features of psoriasis are pathognomonic, so much so that, in cases in which the clinical diagnosis between the two conditions is uncertain, microscopical examination of a sufficient number of sections will decide it. Moreover, in seborrhœic dermatitis, the "bottle-bacillus" and staphylococci are always found in a state of active growth and multiplication, whereas in uncomplicated psoriasis the "bottle-bacillus" is never found, and the lesions are remarkably amicrobial. Again, seborrhœic dermatitis can always be cured, but we know of no method of curing psoriasis or of preventing its recurrence. With regard to alopecia areata, there is no evidence that will bear analysis in favour of its causation by an external infection or of its contagious nature. The section on xanthoma requires revision. It is stated that the substance that produces the yellow colour in xanthoma lesions is fat, but the substance in question consists not of true fat, but of cholesterol-esters; no mention is made here of the high degree of cholesterinæmia that obtains in this condition.

The original edition of this manual, published in 1899, was based on Sir Norman Walker's lectures to students, and the arrangement of the subject-matter adopted was no doubt a convenient one in accordance

with the knowledge and views of the aetiology of diseases of the skin that obtained at that time. In 1908, however, there appeared Darier's "Précis de Dermatologie," by common consent one of the best short treatises on dermatology that has yet been written in any language, in which for the first time a rational classification of skin diseases was attempted. It is a matter for regret that for the most part other authors of text-books have not followed this example. A purely ætiological classification of diseases of the skin is not possible, for, not only is the actual cause of some of them unknown, but certain eruptions, such as urticaria and eczema, are non-specific reactions, which may be provoked by various agents. But a reasonable arrangement is to group together the various forms of eruption due to one specific cause, e.g., those caused by staphylococci or streptococci, and the diseases produced by infection with the same class of organisms, e.g., the bacillary, protozoal, and higher fungus infections, and to classify eruptions of unknown origin or of multiple causation according to their morphological characteristics, e.g., the erythemata, the erythematous-squamous dermatoses, and so on. This method, it seems to us, alone enables the student to obtain an orderly conception of dermatology, and we venture to suggest that in the next edition of Sir Norman Walker's classical text-book a rearrangement of the subject-matter on these lines should be made.

We have long held the opinion that Sir Norman Walker's book is one of the very best foundations on which a student can base his study of dermatology, and the professed dermatologist will find in it much original thought and shrewd philosophy.

SURGERY.

Surgical Operations. Second edition. By E. W. HEY GROVES, M.D., B.Sc., M.S., F.R.C.S., Professor of Surgery, University of Bristol; Surgeon, Bristol General Hospital. London: Oxford University Press. 1925. Pp. 225. 21s.

THIS book is intended as an introduction to operations and to the technical methods by which they are performed. The methods of sterilisation of dressings and the various materials used in operations are described, as well as the usual methods of preparing a patient, and the general organisation of an operation. There follow brief descriptions of several typical amputations, of other operations on the limbs, and on the head and thorax. Much more space is devoted to operations on the abdominal viscera and the genito-urinary systems, and the volume concludes with 36 pages of illustrations of the chief instruments in ordinary use.

The book does not aim at a complete technical description of operative procedures, but merely at giving the onlooker some idea of the aims and methods of the surgeon. It is luxuriously printed and so well illustrated that a nurse or a student can learn enough from its pages to take an intelligent interest in surgical technique unconfused by a mass of detail. It forms an admirable introduction to the larger works to which the student must refer if he wishes really to master the details of operative procedure.

Operative Surgery. Second edition. By J. SHELTON HORSLEY, M.D., F.A.C.S., Attending Surgeon, St. Elizabeth's Hospital, Richmond, Va. London: Henry Kimpton. 1924. Pp. 784. 52s. 6d.

IN the second edition of this work there are certain changes which constitute an important advance and make Dr. Horsley's manual of operative surgery a most valuable one. An entirely new chapter is included on the principles underlying operations for malignant disease. The author deals briefly with the ætiology of cancer, the natural resistance to it, and its metastases. He gives a thoughtful

account of the technical considerations in operations on malignant disease. The scope of the actual surgical procedure is discussed for different types of growths in varying situations, and he gives his opinions on the desirability of the use of such procedures as electro-desiccation and coagulation, and of radium and X rays as prophylactic aids to surgery. The chapter is completed by a short account of the surgical treatment of radium and X ray burns. A considerable number of new operations are described in their appropriate chapters, many of which have not yet found their way into any text-book of operative surgery. In those desperate cases of diffuse septic peritonitis and late intestinal obstruction, in which the patient is overwhelmed by a toxæmia, W. A. Costain has shown that absorption occurs through the thoracic duct. His operation of lymphaticostomy—i.e., of draining the duct in the neck—is described by Horsley, who suggests that it is a procedure worthy of attention in these cases. B. Stookey's method of providing paralysed muscles with a new nerve-supply is fully explained. It consists of anastomosing a free nerve graft—e.g., from a cutaneous nerve—to a motor nerve at one end and to the muscle at the other. Fair results are reported. Two operations for diseases of the heart appear in this edition for the first time; one is the division of the mitral valve as practised by Cutler and Levine. Essentially the technique consists of a thorough exposure of the heart, the passage of a special valvulotome through the walls of the left ventricle, and the division of the cusps. The second cardiac operation is designed for the relief of angina pectoris, and consists of the resection of the superior cervical sympathetic ganglion or its branches, as described by R. C. Coffey and J. Y. Brown. Among other new features are the operations of pulmonary lobectomy by Evarts Graham, chordotomy of C. H. Frazier, and a special method of intestinal resection by H. H. Kerr, which has so impressed Horsley as to cause him to substitute it for his own operation.

It will be remembered that this book does not set out to be a text-book of all operations. Those described are the procedures used and advocated by Horsley, and the book is therefore all the more valuable.

General Surgery. Practical Medicine Series. By ALBERT J. OCHSNER, M.D., F.A.C.S., LL.D., F.R.C.S.I., President of the American College of Surgeons. Chicago: The Year Book Publishers. 1924. Pp. 706.

THIS is a useful review of the surgical literature which appeared during 1924. The book covers the whole field of general surgery, and all important publications have been extracted. The resulting volume will be of value not only to the practitioner but to the active surgeon, particularly in this country, since much of the information is gathered from sources which are inaccessible to him. The book well maintains the admirable standard set up in previous years by its predecessors in this series.

ORTHOPÆDICS.

The Advance of Orthopædic Surgery. By A. H. TUBBY, C.B., C.M.G., F.R.C.S., Consulting Surgeon to the Westminster and Royal National Orthopædic Hospitals. London: H. K. Lewis and Co., Ltd. 1924. Illustrated. Pp. 144. 7s. 6d.

THE six chapters of which this book is composed have appeared as articles in the *Clinical Journal*. In the introductory chapter some sound advice is given on the ways of taking radiographs and on their interpretation, as well as more general considerations. The other chapters describe Congenital and Growth Deformities, Static and Postural Conditions, Infantile and Spastic Paralysis, dealing with the disabilities and deformities caused by anterior poliomyelitis and Little's disease, Reconstructive, Regenerative, and Recreative Surgery, and Re-education. A surgeon

of Mr. Tubby's eminence and experience cannot fail to have much that is worth hearing to say on these subjects, and he has made good use of the small space at his disposal. The statement, however, that no authoritative treatise on orthopædic surgery has been published in this country since 1912 is hardly correct. The authoritative and comprehensive work of R. Jones and R. W. Lovett was published simultaneously in London and New York in 1923. Sir Robert Jones's share in that fine book was such a large one, that it cannot be ignored, as if the work were, like Whitman's "Orthopædic Surgery," a trans-Atlantic production.

There is no doubt that the republication of Mr. Tubby's articles in volume form will be welcomed by practitioners who cannot spare time to study larger treatises.

PRÉCIS DE CLINIQUE SEMIOLOGIQUE.

Diagnostics, Prognostics et Traitements. Eleventh edition. By GASTON LYON. Ancien Chef de Clinique Médicale de la Faculté. Paris: Masson et Cie. 1924. Fr.28.

THIS little French volume seems to correspond with our "Hutchison and Rainy" and to fulfil its purpose extremely well. It deals very carefully with the method of examination of the patient as a whole, and of each particular system, and with laboratory methods of investigation. A comprehensive chapter on prognosis closes with a number of special cases in which a prognosis is urgently required. The concluding part, on therapeutics, includes reference to most of the modern methods. For any student entering upon his clinical work this book would be of value, both for preliminary reading to give him a good general idea of the ground he has to cover, and as a bedside companion when he is learning to examine cases. The practitioner, too, will find interest and information in the up-to-date presentation of work which is liable enough to become an incompletely fulfilled routine.

DIVAGATIONS OF A DOCTOR.

By ALEXANDER JAMES, M.D. Edinburgh and London: Oliver and Boyd. 1924. Pp. 192. 6s.

THE divagations of doctors have led to the production of books which are among the treasures of literature. We need only mention the works of Sir Thomas Browne, and of his near namesake, Dr. John Brown, who wrote those two classics, "Pet Marjorie" and "Rab and His Friends," and in the same class Osler's "Essays." Somewhat lower in the scale are Benjamin Franklin's "Essays," Moxon's "Pilocereus Senilis," and those excellent bedside books by Andrew Wynter "Our Social Bees" and "Curiosities of Civilisation." Dr. James discourses pleasantly upon such subjects as socialism in evolution, juvenile crime, tuberculous disease, and germ- and State-made "millenniumitis." He is no lover of the Education Act of 1872, and many will agree with him in his view that the Act has not produced benefits in accordance with the hopes of its begetters, that it has lessened parental responsibility, and, finally, that most persons do not rightly value what they do not pay for. In lighter vein is the Esculapian Oration on its 150th anniversary, a delightful piece of scientific fooling for the most part, though full of sound sense. As for the occasional songs, they naturally lose some flavour when the occasion has passed, but even so the whole book makes pleasant reading.

JOURNALS.

QUARTERLY JOURNAL OF MICROSCOPICAL SCIENCE. Vol. LXVIII., Part 4. November, 1924. Edited by E. S. GOODRISH, F.R.S. London: Oxford University Press. £1 1s.—The latest number of this excellent journal is essentially like its forerunners of recent

years—that is to say, it exhibits such a variety of contents that specialists in every direction need to consult its pages, while finding therein room for their own contributions to biological science.—Pure embryology finds its exponents in Prof. J. P. Hill, of University College, and a pupil in their contribution to the early development of the cat.—"Natural History," not anatomical, is represented by Prof. W. C. McIntosh, whose exposition of structure and life-histories of the polychæteous annelids is so well known; his communication is entitled Two Tubes of Polyodontes and on the Discharge of the Ova in Thelepus.—Prof. E. N. Pavlovsky, of Petrograd, deals with the anatomy and some points in the development of a variety of scorpions, in continuation of a considerable series of memoirs upon this group of arthropods contributed to other journals in the immediate past.—Two contributions, one by Mr. J. F. G. Wheeler on the Growth of the Egg in the Dab, another by Mr. G. R. de Beer on the Ophthalmic Nerves in Some Fishes, complete the list.

AMERICAN JOURNAL OF PATHOLOGY. Vol. I., No. 1. January, 1925.—In September, 1923, the *Journal of Medical Research*, founded by Dr. Harold C. Ernst, became the official publication of the American Association of Pathologists and Bacteriologists under the control of a strong editorial board with Dr. Frank B. Mallory as editor-in-chief. It now, under the same auspices, becomes the *American Journal of Pathology*, and is to be published bi-monthly, making a volume of at least 600 pages a year. The subscription rates remain the same—viz., \$5.00 in the United States, \$5.50 in Canada, and \$6.00 for foreign countries. The alteration of title is all to the good, for "medical research" embraces far too big a field to be served by any one publication, and the new journal is frankly restricted to pathology, especially morphological pathology. The number contains ten papers. Ernest W. Goodpasture contributes four separate articles dealing with Experimental Herpes and Herpetic Encephalitis in the Rabbit. He concludes that the herpetic virus reaches the central nervous system from the periphery by growth along the axis-cylinders of nerves. Herpetic lesions are associated with the appearance of minute, though characteristic, intranuclear inclusions.—Louise H. Meeker writes on Riedel's struma, describing a case which was associated with remnants of the post-branchial body. The article is well illustrated by drawings of microscopic preparations.—E. R. Saleeby describes a case in which two tumours composed of practically normal bone marrow were found at autopsy in the thoracic cavity, adherent to but distinct from the ribs. He discusses their significance.—In Microglia and the Process of Phagocytosis in Gliomas, Wilder Penfield discusses for the first time the relation of these cells to gliomas; their function is that of active phagocytosis. This article is also illustrated by drawings.—In The Formation of Macrophages, Epithelioid Cells, and Giant Cells from Leucocytes in Incubated Blood, Margaret Reed Lewis brings the tissue culture method to bear on the polyblast question. The technique adopted was simply the incubation of hanging drops of blood.—Studies on Blood Fibrin, by E. W. Schultz, J. K. Nicholes, and J. H. Schaefer. The authors show that the fibrinogen content of blood is increased by tissue injury, including mild liver injury. Liver necrosis causes a diminution in the amount of fibrin which disappears altogether with complete destruction of the liver.—The Relation of Chronic Poisoning with Copper to Hæmochromatosis, by F. B. Mallory. The author met with ten cases of hæmochromatosis in one year's autopsies. The pathology of the condition is fully discussed and the conclusion is reached that the essential cause is chronic poisoning with copper. The source of the copper is the vessel used in the preparation of food or distilled liquors, and the disease is also an industrial one, occurring in workers in copper. The condition develops very slowly, taking some 15 to 25 years to declare itself.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 14, 1925.

THE WELSH NATIONAL SCHOOL OF MEDICINE.

THE histories of the origin and development of the medical schools of the United Kingdom cannot fail to be of absorbing interest to anyone concerned with the broad aspects, or even the details, of medical education. Some of them have grown in established seats of learning, homes of the humanities, where the struggle for recognition has been long and arduous, if, indeed, it has even now entirely ceased. Others have formed, as it were, the nucleus on which the other faculties of the university have crystallised. Yet others have developed out of the private schools of eminent teachers and have always had a frankly utilitarian purpose. But whatever their origins they are now in all essentials stabilised; only one, the Welsh National School of Medicine, whose home is in Cardiff, is still in the making.

The beginnings of medical education in Wales date back to 1893, when, in addition to the teaching of the first-year subjects already in existence as part of the science school, departments of anatomy and physiology were founded at the University College of South Wales and Monmouthshire, Cardiff. In 1909 the Treasury gave a special grant of £1500 per annum to the medical school which enabled a chair of pathology and bacteriology to be established at the Royal Infirmary. It was obvious that the matter could not rest here; the desire for a complete National School of Medicine was strong in the Principality, and in 1914 a deputation representative of university education in Wales presented a memorandum to the Chancellor of the Exchequer on the proposed completion of the medical school. In the next few years the whole question of university education in Wales, and especially medical education, was considered by various important bodies, including a Royal Commission presided over by Lord HALDANE, which numbered Sir WILLIAM OSLER among its members. The Royal Commission recommended that the school of medicine should be constituted an independent college of the University of Wales, and the medical faculty, the Board of Medicine of the school, and the managers of the Cardiff Royal Infirmary have endorsed this recommendation. More recently the matter came before the Council of the University of Wales, which decided that the school should be separated from the local administration of Cardiff College and should be established as a constituent school of the university with its own administrative authorities, directly responsible to the university. The reasons which influenced these responsible authorities in coming to this decision are difficult to appreciate without a complete understanding of conditions, but the question of administration must have weighed very heavily with them. Under the existing conditions there are upwards of ten different bodies or committees which in one way or another exercise jurisdiction over the school of medicine. Some of them, and some of the important among them, are of unwieldy size; while of

their members it may justly be said that the majority can have little or no first-hand knowledge of the needs of a modern medical school. In an old-established institution a multitude of committees may not be harmful; they may have been called into being to meet existing needs; they may even at times serve as useful safety-valves. But a young, expanding school must have freedom to grow; it needs the wise guidance of the knowledgeable few rather than the control of the uninstructed many. Another cogent reason for the fusion with the University is the undoubted desire of the Welsh people for a National School of Medicine. A practical proof of this was given in the response to an appeal for funds made on behalf of the school by the University of Wales to the Welsh people. Not only was money obtained in the form of subscriptions from individuals all over the country, but an $\frac{1}{2}$ d. rate was given by every local authority in the Principality. Now the Federal University of Wales consists of four constituent Colleges: those of Aberystwith, Bangor, Cardiff, and Swansea, in all of which Welsh students can obtain University teaching in most faculties. But there is only one medical faculty, and it is part of Cardiff University College. It is not unnatural to suppose that the rest of Wales may ask why the National School of Medicine should be the property, as it were, of a single one of the constituent Colleges, especially if the school itself is dissatisfied with this close association. This consideration might well have weighed with the Federal University, which, as recipient and distributor of all grants in aid of the University and its Colleges, is naturally concerned lest the school might become a financial burden if this support from the rates were withdrawn.

There is, of course, another side to the question, or there would be no opposition to the separation of the school of medicine from Cardiff College. This opposition is genuine and not merely the expression of respect for vested interests. But it seems to be based chiefly on a misconception as to what is meant by separation. If separation meant the withdrawal of the school of medicine from the academic life of Cardiff College and from association with the Federal University, few would be found to advocate it. But, as Sir CHARLES SHERRINGTON, P.R.S., points out in a judicial article in the *Western Mail* of Feb. 7th, the very reverse is intended. If the proposals are carried out the school will be brought into closer connexion with the University itself, while the existing cross representation between the academic authorities of the school and the College will continue. The school will only be independent in the same sense that the College is; it will, of course, be a constituent part of the Federal University, as the College is, and administratively and financially it will be governed by the University. An argument against separation, one upon which considerable importance seems to be placed locally, is that the general culture of the medical students will suffer if they are separated from their fellow undergraduates in the other faculties. But this argument scarcely bears examination. The social amenities of the older residential universities can never be enjoyed in modern universities situated in large cities. A student may spend six extremely profitable years at a London hospital without exchanging one single word with an arts or a divinity student. In working hours there is an inevitable tendency for birds of a faculty to flock together; in their social intercourse there is not the slightest reason why the different faculties in Cardiff should not mingle in the future as they have done in the past. The whole weight of considered opinion is so strongly in favour

of the proposed separation as the natural solution of a difficult situation that it cannot but come to pass. It is to be hoped that it will not be unduly delayed, so that the Welsh National School of Medicine may develop unhampered along the progressive lines sketched out by Sir WILLIAM OSLER.

HYGIENE OF THE NOSE AND NASO-PHARYNX.

THE function of the nose is to warm, moisten, and filter the inspired air; and this function is performed in such an efficient manner that in normal conditions the air, by the time that it reaches the naso-pharynx, is sterile, saturated with aqueous vapour, and raised to the body temperature. The current of air, passing in through the narrow anterior nostrils in a rapid compact stream, on entering the wider irregularly shaped nasal passages, slows down and is broken into a number of sluggish eddies which, coming into intimate contact with the warm moist surface of the mucous membrane, deposit their dust and receive warmth and moisture. For this purpose a considerable activity is required from the mucous membrane; it has been reckoned that it contributes half a pint of water a day to the inspired air. It is well equipped for its work, being freely supplied with blood to warm, glands to secrete moisture, and ciliated epithelium to sweep the mucus-entangled dust backwards to the throat. If the normal activity of secretion is disturbed, as in anæmia or dyspepsia, dryness results; or, if part of the mucosa is replaced by scar-tissue, a scab of dry mucus forms. Hence the importance, in operations in the nose, of interfering as little as possible with the normal mucous membrane.

Under the healthy conditions of a simple open-air life these functions are ordinarily well performed, any extra mucus is easily expelled by blowing the nose, and artificial assistance is quite unnecessary and, indeed, likely to be harmful. It was remarkable, in the war, that soldiers living under primitive conditions, in wet and muddy trenches, were seldom afflicted by catarrhal troubles; but among those living in the circumstances of modern life in civilised countries, especially in towns, these troubles are only too common; in the United States they are especially frequent, and the predisposing factor is probably the over-heating of houses which results from the prevalent system of central heating. The proper cure for catarrh is, therefore, a return to the simple life; unfortunately, this is rarely possible, but the nearer it is approached the better. Sufficient open-air exercise and, above all, well-ventilated rooms and houses are the great preventives; draughts are less severe when plenty of windows are open, but a small opening into a hot room causes a concentrated current of air. The custom, common among nurses, of cleaning the nostrils of infants with a pledget of cotton-wool is unnecessary, though harmless; but, as soon as the child is old enough, he should be taught how to blow the nose. The proper method of performing this simple act is to close one nostril with the finger and to blow steadily and strongly down the other, and then to repeat the process through the opposite nostril. Both nostrils should never be closed at once during the blowing; this is obviously ineffectual in clearing the nose, and may blow discharge through the Eustachian tubes. Sniffing is an unpleasant and unsocial habit; but if a child cannot blow the nose properly, it is better even that he should sniff and swallow stagnant secretion than leave it in the nostrils; the catarrh or obstruction

should be cured rather than the child punished for sniffing.

Nasal obstruction is a common cause of chronic catarrh and of susceptibility to colds; mucus tends to stagnate behind such an obstruction and to form a nidus for the growth of micro-organisms. It often, however, takes years for such catarrhs to develop seriously; cases of deviation of the septum frequently suffer but little inconvenience in their youth, and only develop much discomfort from catarrh when middle age is reached, after which time the condition steadily becomes worse. In childhood, adenoids are the common cause of persistent catarrh, and are themselves due to repeated attacks of catarrhal inflammation; the possibility of their prevention is a matter of importance. Something can be done by attention to ventilation, open-air exercise, and general hygiene; and something by seeing that young children learn to remove excessive secretion by proper blowing of the nose. In the early stages, when some nasal obstruction has developed, breathing exercises regularly performed improve the ventilation of the naso-pharynx, help to remove stagnant secretion, and so break the vicious circle; but when the naso-pharyngeal tonsil is so enlarged as decidedly to obstruct nasal respiration, breathing exercises will not effect a cure, and may do harm by increasing the deformity of the chest. The use of irritating snuffs to encourage sneezing has at times been widely recommended; theoretically, at least, it would appear that irritation of the delicate nasal mucosa must be hurtful. "Handkerchief drill" in schools, to encourage proper blowing of the nose, is excellent and should be more generally adopted. In infants and young children with catarrh, 20 or 30 drops of warm normal saline lotion may be dropped down each nostril from a fountain-pen filler while the head is thrown back; this undoubtedly removes secretion and clears the nasal obstruction, while it appears to be quite harmless and to cause shrinkage of the adenoid in its early stage of catarrhal swelling. There is no danger of choking an infant if not more than 30 m is used at a time. In older children, over 6 or 7 years of age, and in adults, the effect is best obtained by washing out the nasal passages. Much controversy has arisen over this, the principal objection being that it can cause inflammation and suppuration of the middle-ear. But it does relieve and cure many cases of nasal and naso-pharyngeal catarrh, and, if certain simple precautions are taken, there is little danger of spread of inflammation to the ear. The lotion should be at or slightly above body temperature; it must be quite unirritating and painless and should consist of normal saline solution, or of a similar isotonic mixture of harmless salts; plain water is hypotonic and damages the delicate epithelial cells, and any powerful antiseptics are harmful. It must never be used while there is a raw surface resulting from an operation, as after the removal of adenoids, or in the acute stage of a cold, but is valuable when the "sticky" stage has been reached. The flow should be interrupted if any gagging occurs, and this happens automatically when a syringe, and not a gravity douche, is employed. Probably the best instrument is a 2 oz. indiarubber ball with a short firm nipple of the same material moulded in one piece; it is easily sterilised by boiling, and is too small to produce any considerable pressure; if there is unilateral obstruction, as from a deflected septum, the syringe is applied only to the obstructed side, so that there is a free exit for the lotion from the other. The patient fits the syringe to one nostril, inclines the head forward, and breathes deeply through the open mouth, while he slowly squeezes the ball

empty and the lotion trickles out by the opposite nostril; this is ordinarily repeated through the other nostril, and then the nose is gently blown as already described. A child of 6 or 7 years of age can easily do this for himself, and soon appreciates the increased comfort it brings to a stuffy nose; it is better that he should do it himself, for he immediately relaxes the pressure if he gags. He must be particularly careful not to close both nostrils at this stage, or a cracking may be felt in the ear, and it is in this way that the ears may become infected. But such an accident is certainly very rare, and the good which results from this procedure in cases of catarrh is very definite; for some patients susceptible to colds, its regular use through the winter months serves as a decided preventive.

REX v. BATEMAN.

THE decision of the Court of Criminal Appeal to quash the conviction of Dr. PERCY BATEMAN corrects a manifest miscarriage of justice, and will be in every way satisfactory to the medical profession. A report of the arguments of counsel appears upon another page, but the Court, while quashing the conviction, decided to give their considered reasons in judgments later. We regard the result with peculiar satisfaction, not only because Dr. BATEMAN is to be congratulated upon having been saved from a period of degrading imprisonment which he had done nothing to deserve, but because a precedent has been established for the reviewing of a jury's verdict which had been delivered upon an interpretation of medical evidence. New facts were not brought forward, but the old facts were made to wear their right interpretation. To those who could understand the scientific evidence as it was given, the original verdict appeared wrong. The story of the circumstances in which Dr. BATEMAN's patient died, and in which he was convicted of manslaughter by criminal negligence, has been read and considered by a large number of his colleagues, liable through the nature of their practice to find themselves performing their professional duties in a like situation. These have, of course, been more capable than any jury of basing a correct opinion upon the clinical evidence. They will have seen, as indeed did the jury, that the injuries following a complex presentation were the cause of death, but did not imply such negligence on the part of the operator as would justify his conviction for manslaughter. Medical men will also have appreciated, as a jury would not even though properly guided by a judge, that the physical injuries that affected the deceased did not by themselves prove guilt, but that their occurrence was equally consistent with complete innocence. And under the conditions in which Dr. BATEMAN found himself, in spite of the exercise of all reasonable care and skill, such tragedies may fall out. We have not here a specialist working in the ward of a hospital or nursing home, or in the convenient environment of upper or middle-class practice, but a general practitioner attending a poor patient in a poor man's room; and with the conditions obtaining in such places many general practitioners are familiar. The conditions determined the tragedy. Medical men must have wondered what standard of skill and care had been laid before the jury by the judge who tried Dr. BATEMAN as necessary for a medical man to reach in order to avoid a criminal charge on the death of a patient in whose case, in popular phraseology, "Something had gone wrong."

Annotations.

"Ne quid nimis."

CANCER AND GOITRE.

GOITRE is endemic in certain parts of Switzerland. That country has also the highest death-rate from cancer, and this high death-rate is due mainly to the frequency with which the upper part of the digestive tract is attacked by cancer. Thus the mortality per 100,000 from cancer of the oesophagus and stomach in males is 75.4 for Switzerland, as compared to 21.6 in England and Wales; in females it is 46.2 for Switzerland, 16.2 for England and Wales. For all other organs combined the rates are—in males, 45.7 for Switzerland, 55.7 for England and Wales; in females, 72.0 for Switzerland and 86.5 for England and Wales. These facts suggest the possibility that a common factor may be involved in the incidence of goitre and of cancer, and raise the further question whether a condition of hypothyroidism renders the body more liable to develop cancer.

The current number of *Biometrika* (vol. xvi., December, 1924) contains a paper by Dr. Percy Stocks in which he tries to answer these interesting questions by a comprehensive statistical investigation. He finds that in those regions in Switzerland where goitre is frequent there is also a higher incidence of cancer of the stomach and oesophagus than in areas where goitre is less frequent. The same is stated to hold good for other goitrous regions in Europe and in the United States. Graves's disease, on the other hand, shows a negative correlation with cancer mortality. A consideration of 1000 post-mortem records from the Middlesex Hospital shows that enlargements and other anomalies of the thyroid gland are more frequent in cancer cases at death than in non-cancer cases, and these anomalies are of the types usually associated with depressed thyroid function. The general conclusion is drawn that defective functioning of the thyroid gland is favourable to the incidence of cancer of the stomach and possibly of other organs also, and it is suggested that the administration of iodine after middle age, as practised in Switzerland for prophylactic purposes against goitre in young people, might result in diminishing the incidence of cancer.

A number of objections suggest themselves to these conclusions. The statistical evidence does not show that cancer of the stomach is more frequent in individuals suffering from goitre. It only shows that in some countries it has a similar regional distribution as goitre. It is known that goitre is more frequent in women than in men, while cancer of the stomach is more frequent in men than in women. That is contrary to what we would expect if hypothyroidism predisposed to cancer. Moreover, no reference is made to countries like Holland—which are not goitre countries, but where cancer of the stomach has an exceptionally high incidence. If a direct relationship between the incidence of goitre and of cancer of the stomach existed, there ought to be clinical evidence in goitrous countries such as Switzerland of a frequent coincidence of the two diseases in the same individual. So far as we are aware so such evidence exists. The argument based on post-mortem findings is fallacious, because cancer is a chronic disease entailing prolonged inactivity of the patient with treatment by drugs. That in itself might account for the abnormalities found. The slightly diminished incidence in Graves's disease is readily explained by the fact that Graves's disease has a much higher mortality than goitre, especially if we include affections of the heart resulting from the disease. It is, moreover, not an endemic disease, and, unlike goitre, is not dependent on environmental conditions which affect the whole population living in a district where the disease occurs. We mention these objections, not because we wish to deny that a correlation between thyroid activity and incidence of

cancer exists, but in order to illustrate the limitations of statistical methods in investigating such a complex medical problem, even when they are applied with the competence and care which distinguish Dr. Stocks's investigation. If the relationship between thyroid activity and cancer incidence exists which Dr. Stocks postulates, then there are direct methods available to demonstrate it. The basal metabolism is generally recognised as a measure of thyroid activity. By determining the basal metabolism in various diseases of the stomach, including sufficiently early cases of cancer, it should be possible to obtain more direct evidence on the interesting question which Dr. Stocks has raised. Until such direct evidence is obtained, the suggestion of indiscriminately dosing with iodine must be considered premature. In Switzerland the suspicion has arisen that the continued use of iodine to prevent goitre may lead to the production of exophthalmic goitre.

"BRONCHIAL SPIROCHÆTOSIS."

MUCH has been written in recent years upon a pulmonary condition to which the term bronchial or broncho-pulmonary spirochætosis has been applied. Dr. Y. Schwarz recently described in THE LANCET¹ five cases which he had had under his care in Cairo, while a case in a suspected tuberculous subject at Montana was described in our correspondence columns² on Jan. 17th. In the last-named case a radiograph showed a definite opacity at the apex of the right lung. Bronchial spirochætosis was first described by Castellani,³ who based his diagnosis on the presence of numerous spirochætes in the sputum of two cases of hæmorrhagic bronchitis observed by him in Ceylon in 1904. Since that time a considerable literature has gathered round this subject. Macfie,⁴ Galli-Valerio,⁵ Violle,⁶ Dalimier,⁷ Dargallo,⁸ Farah,⁹ Mendez,¹⁰ Robert,¹¹ Korthof,¹² Carini,¹³ Browne,¹⁴ de Mello,¹⁵ Risquez,¹⁶ and Faust¹⁷ have reported cases from Africa, France, Italy, Switzerland, Spain and Portugal, England, Brazil, Venezuela, China, and Dutch East Indies. These papers, though informative regarding the cause of the disease, its treatment, and manner of spread, are curiously silent regarding its true pathology. Some underlying pathological condition has been presumed to exist, but the possibility of the spirochætes complicating other well-known pulmonary conditions, such as tuberculosis, appears to have been overlooked. The question of the relationship of the spirochætes of the mouth to one another and to the *Spirochaeta bronchialis*, described by Fantham,¹⁸ in 1915, needs clearing up. Fantham regarded this organism as distinct from other spirochætes occurring in the mouth, whereas Schwarz,¹ in his recent paper, figures these organisms associated with fusiform bacilli as in the case of the familiar Vincent's spirochæte; in both instances recorded pyorrhœa alveolaris was present, in the pus of which these latter organisms abound, and Vincent¹⁹ himself believes *S. bronchialis* and *S. vincenti* to be identical. Moreover, the specificity of *S. buccalis* and *S. dentium*, which can be universally

demonstrated in the oral cavity, is by no means decided. Mühlens,²⁰ in discussing this question, declares that German pathologists regard spirochætes in the sputum as being of little importance. These organisms, he says, are found in enormous numbers in inflammatory conditions of the mouth and pharynx, and, under suitable conditions, may spread to the lungs. He is therefore of the opinion that broncho-spirochætosis is not recognisable as a characteristic disease. Pons,²¹ basing his opinions on observations made in Saigon, has also come to the same conclusion. Dental caries, he finds, greatly favours the presence of spirochætes in the sputum. He was fortunate enough to secure an autopsy of a patient who had been expectorating spirochætes in blood-stained mucus, but no pleuro-bronchial lesions could be found to account for it. In the bronchial mucus itself there were no spirochætes, but as the higher portions of the respiratory tract were reached, they became more numerous. It appeared logical to conclude that the spirochætes in the sputum before death were identical with those occurring in the mouth, so that, in considering the morphology of these spirochætes, he is driven to the conclusion that it is practically impossible to differentiate *S. buccalis* from the so-called *S. bronchialis*.

Under these circumstances, it is surely somewhat venturesome to speak of bronchial spirochætosis complicating pulmonary tuberculosis as in cases quoted by Bloedorn and Houghton,²² and Korthof¹² and to a recent review by Delamare.²³ In the cases recorded by Pons, the probable sequence of events is that an invasion of the respiratory tract by spirochætes from the mouth takes place under conditions which facilitate their multiplication as in pulmonary tuberculosis; for, when the patient makes a good recovery from the latter, the spirochætes tend to disappear. The authenticity of this condition having been criticised upon unquestionably sound evidence, it would be advisable for the whole matter to be reconsidered, in light of recent facts, before accepting, without cavil, bronchial spirochætosis as a distinct clinical and pathological entity.

THE ÆTIOLGY OF ALOPECIA AREATA.

THE ætiology of alopecia areata has long been the subject of worry among its victims, who express disappointment amounting to indignation that neither prevention nor cure of this disfiguring malady is in their power. It is at any rate possible to comfort them by the assurance that though a family tendency to patchy baldness may exist, the majority of dermatologists see no reason to regard the condition as contagious. Sir Norman Walker, in the new edition of his book, which we review in another column, is one of few who still clings to the suspicion that alopecia areata is due to an external infection. But the evidence for this theory will hardly bear analysis. Haldin Davis and others have shown the explanation of at least some of the alleged epidemics in schools and institutions to be imitation of one or two genuine cases; the interest aroused by the earlier cases has led to other children "plucking" their hair, producing what may be called "alopecia artefacta"; others, as Sabouraud points out, have been epidemics of impetigo, the impetiginous areas on the scalp having become denuded of hair. The familial incidence of alopecia areata is much less common than of psoriasis; yet Sir Norman Walker does not suggest that the latter disease is contagious, but is inclined rather to make light of the hereditary factor in its ætiology. A study of the evolution and nosology of alopecia areata, and of the mode of formation and characteristics of the exclamation

tion-mark hair, leads inevitably to the incrimination of the sympathetic fibres supplying the hair-bulbs. A point of great significance is that in the formation of the exclamation-mark hair there is an alteration in the distribution of the pigment, which becomes collected into clumps at the distal end, while the proximal part is completely depigmented. This pigmentary change is exactly analogous to that which occurs in vitiligo, and the two diseases are frequently associated, one or both being common in Graves's disease, in which disturbance of the sympathetic is so predominant a factor. It is impossible to reconcile these facts with the theory of external infection. The exhaustive researches of Sabouraud, himself at one time a protagonist of this theory, as detailed in his latest work on diseases of the scalp, should surely have disposed of it.

THE ANTIQUITY OF MAN.

IT is strange to reflect that at the time of the foundation of THE LANCET it could never have occurred to its average reader to doubt that an act of special creation had introduced his first parent to this earth in a condition of human, if bucolic, completeness at a date, fixed at some 4000 years B.C. Yet now Sir Arthur Keith has given us two volumes of familiar discourse on the habits and features of man and his pre-human ancestors, to which we referred last week,¹ in which the reader is referred back to a period 200,000 years earlier, and told that there is still a question as to whether the time estimate is not still too conservative. And following hard on the re-issue of Sir Arthur Keith's book comes news from Africa of a new anthropological find promising to be one of the most significant in the history of geological excavation. The fossilised skull brought to light through the enthusiasm of Prof. Raymond Dart and his colleagues of the University of the Witwatersrand, Johannesburg, and described by him in last week's issue of *Nature*, is judged to be that of a child of six, from the fact that the first molar only, of the permanent dentition, is erupted. It is particularly interesting in that there has been preserved in the limestone matrix a more than usually complete picture of one cerebral hemisphere. A certain amount of caution has to be exercised in drawing conclusions from the bony formations of a skull so young as this. As is well known, the young of allied species tend to resemble each other more closely than do the adults, and the distinctive prominences and contours of the skull are not developed until later years. But there appears to be no such change in the general proportions and pattern of the brain, so that when we find in this child a brain actually larger than that of the adult chimpanzee, and presenting a rounded outline in striking contrast to the flattened parietal appearance of the ape brain, we cannot refuse to admit the claim of the individual to a proportional psychological development of the higher mental functions. The "parallel sulcus" balances the general expansion of the cerebrum by providing a distinctly pithecoïd feature. In the skull also a similar mixture of humanoid and anthropoid features is found. The brain development is reflected in the proportions between the brain case and the facial portion, which place the fossil about midway between the young gorilla and the modern human. The same intermediate character is seen in the position of the foramen magnum, from which the degree of uprightness of gait may be deduced. The "head balancing index" used by Prof. Dart to illustrate this point places the new specimen between the chimpanzee and the Rhodesian skull. The orbits and nose are distinctly human in their formation, as are the teeth. The jaw, however, is massive, particularly so considering the youth of the individual, although the fashioning of it is human, in the slenderness of the

ramus, the absence of a "simian shelf," and the relatively vertical direction of the anterior symphyseal outline. It has, in fact, attained a degree of development which brings it into line with Heidelberg man. To give this specimen a definite place in the evolutionary series would be premature at present; it will doubtless arouse as much expert discussion and controversy as its predecessors. But those whose pictorial imagination likes to hasten in advance of the slower methods of anthropometry will probably associate the name *Australopithecus africanus* with a race of creatures somewhat larger than chimpanzees, walking habitually upright, if with a rather stooping gait, living probably a solitary or limited family life (for the great link of speech had not yet been acquired), but able to profit by experience and to store memories with sufficient adequacy to make headway against the difficult environment of the African climate and dangerous veldt life; they could lay down by the use of eye, ear, and hand those new associations, new deductions, and new meanings which formed the germ of *Homo sapiens*.

Meanwhile the more cautious will turn, with even greater enthusiasm than before, to the new and revised edition of "The Antiquity of Man." The issue of this manual of up-to-date information is indeed timely, for only those acquainted with the wealth of knowledge so charmingly presented therein can appreciate and assess the value of the new skull. The general matter and manner of the book are well known. The author takes us out on a tour of the world, choosing the geographical method rather than the historical for the presentation of his material. Wherever we alight he beguiles us with easy conversation as to the surrounding country, the folk-lore, and the history of the area around us, until we are ready to be introduced, almost personally, to the dead and gone inhabitants of many ages past. We see them at work, at play; we consider their features, their ornaments, their works of art, their implements, and household possessions. And almost without our realising it we are instructed in the latest scientific knowledge and the most elaborate specialist opinions about them. Upon Sir Arthur Keith has descended the mantle of the prophet Ezekiel, who prophesied unto the dry bones so that they lived and stood upon their feet, an exceeding great army. Since the publication of the first edition, ten years ago, new material has come in from all parts of the world: Palæolithic Englishmen in the Mendips; early roundheads at Solutré; rugged Nordic types at Bonn; at Ehringsdorf, Neanderthal men intermediate between Heidelberg man and the French Neanderthals; the illuminating Ghar Dalam caves of Malta, and, finally, the extremely significant Talgai man of Queensland and the African series of discoveries culminating in *Homo rhodesiensis*, that pathetic Pleistocene sufferer from toothache and "rheumaticks." With all these Sir Arthur Keith deals, weaving them into the matter of his earlier edition with that combination of erudition and fascination so peculiarly his own. The first two chapters of the second volume are devoted to the Broken Hill skull, which is compared, whimsically enough, with that of Sir Thomas Browne, and is placed on a line of its own, separated off from the general human stem somewhere in the Pliocene. The later chapters deal with such subjects as Heads, Brains, and Teeth, as found in early man, and the final one discusses some general conclusions, which are well illustrated in the diagram that forms the frontispiece. The original evolutionary hypotheses were direct descendants of the popular scientific custom of arranging all known objects, from the angel to the stone, in order of their elaboration, and the early evolutionists did but give a shake to the "Echelles des êtres" and turn them into living stairways or escalators, each step still neatly placed in its order. Such conceptions have long since given way to the simile of the "tree of life," and that branch of the tree which deals with man has many

¹ The Antiquity of Man. Revised edition. By Sir Arthur Keith, M.D., F.R.S. London: Williams and Norgate, Ltd. 1925. Two volumes. With 266 illustrations. Pp. 753. 25s.

spreading side-branches. The only relics that Sir Arthur Keith places on the direct line of modern European ancestry are the Cro-Magnon, Combe Capelle, and Grimaldi men. The Talgai and Boskop specimens lead directly on to modern Negroid and Australoid types respectively, but all the other traces that research has revealed do but tell us of the many abortive efforts made by Nature to produce that strange phenomenon *Homo sapiens*. It will be interesting to see where *Australopithecus africanus* takes a place in the genealogical tree when a further edition of this popular classic is called for.

THE HÆMOPHILIC BLOOD.

It was pointed out by the late Prof. Baylis in his monumental "Principles of Physiology" that the current theories of the coagulation of the blood are merely a schematic representation of observed facts and that the actual existence of the numerous postulated "pro" and "anti" bodies is as unlikely as that of the amboceptors and haptophores of Ehrlich. The hæmophilic diathesis has always been a peculiarly happy hunting ground for the exponents of this particular class of theory, and few workers in the field have omitted to locate the cause of the failure of the clotting process in a deficiency of one or other of these hypothetical factors. The work of Pickering in this country seems to have proved the non-existence of "anti-thrombin" at any rate, and consequently to have endangered the safety of the whole fabric of the hypothesis, while the latest observations on the hæmophilic diathesis lend no support to the current conception. The authors of these most recent observations, Drs. Hans Opitz and Hedwig Zweig,¹ of Breslau, although obviously starting out with a marked bias in favour of the school of Morawitz and Howells, were forced to the conclusion that the hæmophilic diathesis does not depend on the absence of some one link in the coagulation process but is the expression of a profound alteration in the constitution of the blood. Using as the subjects of their research three well-recognised hæmophiles, these workers first tested the relative power of the constituents of normal and hæmophilic blood in bringing about the inception of the clotting process in whole blood of normal and hæmophilic origin. They found that the constituents—serum, red cells, hæmoglobin solution on platelets—from either hæmophilic or normal sources were equally active in bringing about clotting in normal blood, an observation which points to no lack either of kinase or prothrombin in hæmophilic blood. With hæmophilic whole blood they found the case somewhat altered; here the individual constituents of hæmophilic blood showed themselves somewhat less active than those of normal blood. From this they concluded that the actual cause of the comparative failure of coagulation in hæmophilia must lie in a slowing down of the process of formation of the fibrin ferment. Their observations, however, did not end here; extending them to include not only the hæmophilic patients but also their mothers they found that the blood of both presented three striking departures from the normal. In the first place, both showed an increased resistance to osmosis on the part of the red cells; in the second both showed a somewhat high calcium content; and in the third the serum from both was completely lacking in the trypanocidal power normally always present. Unfortunately, the observations were not extended to include the non-hæmophilic offspring, but as they stand they appear to indicate that the onset of hæmorrhage in hæmophiles is in the nature of an accident, dependent probably upon a deficiency in fibrin ferment, but occurring in individuals belonging to families characterised by the possession of an abnormal type of blood. This view would add the hæmorrhagic

diathesis to that group of diseases of which acholuric familial jaundice and the sickle-cell anæmia of negroes are the two best recognised examples.

THE CRITERIA OF BACILLARY SPECIES.

A CAREFUL and thorough examination of 89 strains of tubercle and acid-fast bacilli by Dr. G. S. Wilson, of Manchester, is published in the last number of the *Journal of Pathology and Bacteriology* (1925, vol. xxviii., p. 69). Culturally the customary five groups were recognised—human, bovine, avian, cold-blooded, and saprophytic acid-fast. Agglutination reactions show considerable overlapping, and it is not clear that a smegma or timothy grass bacillus could certainly be differentiated from a human tubercle bacillus by this means. Absorption of agglutinins gives clearer distinctions and delimits four groups. But the human and bovine strains remain indistinguishable by these serological tests, and there is no evidence at all of any subgroups within either species. The investigation is of great inherent value and of special interest as raising once again the question of what we mean by "species" among bacteria—a matter of moment to pathologist, epidemiologist, and general biologist. We have here a case where two sorts of bacilli are clearly distinguishable by their pathogenic effects: in crude summary the human bacillus causes phthisis in man while the bovine bacillus does not. The two are almost equally different by their growth on artificial media and by their pathogenicity to animals, though here the distinctions are perhaps quantitative rather than qualitative. But by the most delicate tests which we can apply their chemical constitution is more or less identical, and from a study of the great bulk of analogous examples we know that these tests are tests of the differences between "species" as commonly understood. Other examples of the same kind of thing are known. No one supposed that the cause of epizootic abortion of cattle had anything to do with the cause of Malta fever until the bacteriologist found that he could distinguish between organisms coming from the two sources only when he was pressed to bring into play his most elaborate armamentarium by the insistence of the epidemiological fact that the two diseases had apparently no connexion with or relation to one another. In his turn the clinician has been forced by the bacteriological evidence to look into human cases more closely and has found two or three examples of what certainly appear to be infection by *B. abortus*, but these exceptions only emphasise the pathogenic distinction between the two "species" of *Brucella*. Similarly, the practical difference between the organisms of plague and pseudo-tubercle is that the former is pathogenic to rats while the latter is not; culturally they are nearly or quite identical, and animals may be protected against plague with a pseudo-tubercle vaccine. Conversely, we have examples of bacilli which are serologically but not pathogenically distinct. The diphtheria bacillus has been dissected into a number of agglutination strains; the same antitoxin will neutralise their toxins and there is no evidence that they vary among themselves in their pathogenic relations to man. The types of pneumococci, which are beginning to seem less clearly distinct from one another than they were at first, are differentiated by agglutinin and precipitin reactions; one is evidently more important than the others in causing acute lobar pneumonia, but that and other characteristic lesions may be due to any of them. The agglutination groups of the gonococcus seem to have no reflection in clinical practice, nor have those of the meningococcus apart from the question of curative serum.

It is, of course, tempting to speculate as to what this may mean in terms of evolution. Parasitism is presumably a secondary character, and parasitism of warm-blooded animals is certainly a late acquisition; we should therefore be inclined to look to other characters as affording sound diagnostic criteria. On the other hand, the fact of parasitism and especially

¹ Jahrbuch f. Kinderheilkund. 167, den Dritten Folge, 57 Band, Heft 3, October, 1924.

the host which is parasitised may well be determined by chemical characters which are the basis of serological distinctions. And our practical men will certainly not be content with a classification which tends to ignore one of the features of a bacillary "species" which is most obvious to us. The evolutionary aspect leads us also to reflect that a thousand years with us is as but a day or two with organisms which can double their numbers in half an hour. We know, too, that current cultures may be dissected into races which are culturally, serologically, and pathogenically distinct, and with this going on under our eyes we should be the more ready to believe that it may happen and may have happened in a wider world than a Petri dish. The clinical counterparts of this seem less definite. But without going into detail the change of type in scarlet fever and the alastrim-smallpox facts are very suggestive; unfortunately, in neither case can we examine the unknown causative agent. At the extremes there are two schools of thought. The hundred per cent. bacteriologist looks upon an infectious disease as the specific result of an organism; to him the same organism means the same disease, and if the organisms are different, then their diseases must be different. To the out-and-out epidemiologist, on the other hand, a disease is a thing quite apart from its cause or supposed cause, and an epidemic has specific characters which can be defined without reference to bacteriology. The common-sense view is that the diagnostic differentiation of both diseases and bacteria may obviously be expected to improve in the future as it has constantly improved in the past, and that no one can lay down which are the best and most reliable characters on which to distinguish and classify bacteria any more than similar criteria for classifying animals and plants in general can be defined. Broadly speaking, and despite many complaints to the contrary, no one doubts very seriously that the customary "species" of the zoologists and botanists represent things which are in effect different from one another; one set of criteria are used in one place, another set in another group, and it is on a general summation of differences rather than by the diagnostic tests which are used for quick practical work that one "species" differs from another. What would be very helpful to the bacteriologist would be some line through which he could get a comparison of the validity of the criteria he uses with those favoured by the systematic biologist. As the bacteria have no obvious structure, the comparison must be made on the only available ground, that of serological distinction. We know roughly that zoological "species" are generally serologically different from one another, but there is room for much more detailed information, especially as to the affinities of known races and varieties. A comprehensive serological dissection of the cabbage in its multiform appearances in cultivation would be illuminating. Is curly kale related to brussels-sprouts as the gonococcus to the meningococcus, or as the types of pneumococci, or as the groups of diphtheria bacilli, or as human and bovine tubercle?

CONTROL OF THE GLOTTIC APERTURE.

RECENT experiments by Sir Charles Ballance¹ on anastomosis of various nerves to the recurrent laryngeal, in an attempt to restore function to a partially paralysed larynx, and the results attained by him and also by Dr. C. Frazier² and Chevalier Jackson, of Philadelphia, on the human subject suffering from abductor paralysis, have drawn particular attention to the region of the glottis. The physiological meaning of respiratory opening of this aperture has so far received but little study, and the solution of the problem has been immersed in shadow. A contribution to the subject was recently made by Dr. Siegmund Schumacher in the *Wiener Klinische*

Wochenschrift,³ where the author describes how elastic fibres in the crico-arytenoid joint cause the glottis to take up what is known as the cadaveric position on those occasions when the dilator and sphincteric muscles are out of action, or have been removed by dissection. The joint is compared in its mechanical aspect to those found in the vertebral column, the similarity being noticed in the fact that the spine springs back into its former position after it has been disturbed, because of elasticity of inter-vertebral discs and ligaments. The corresponding property of the arytenoid cartilages, by virtue of which a certain position is taken up, leads to the necessity for active muscular contraction when any other position except the cadaveric is to be assumed. Consequently, it is found that during health these cartilages, and therefore the vocal cords actuated by them, are drawn apart or brought together by the action of two sets of muscles—namely, the abductor and adductor groups. So it is seen why dyspnoea occurs in cases of double abductor paralysis; because when one group of muscles is out of action, tonic contraction of the opposing set causes undue movement in a certain direction. And when all the intrinsic laryngeal muscles are paralysed, the vocal cords assume a position determined by elasticity of the crico-arytenoid capsule, together with that of the conus elasticus, reinforced by the action of fat cells contained in the capsule; these cells recoil after compression due to any movement away from their resting position. It is also pointed out in the paper that the vocal cords are quite slack in the position of full inspiration, an observation which renews the doubt felt as to the truth of what is usually described as the mechanism of phonation—namely, by stretching of these structures. Dr. Schumacher, in brief, brings notice to a most important organ, and illustrates the importance of observation of detail, without immediate regard to the clinical aspects of the subject.

THE OUTSPOKEN AND THE INDECENT.

WE have received from a correspondent a protest against the lack of reticence which he finds to mark the modern novel. "A short time ago," he says, "a weekly literary journal gave a list of the 'best-sellers' among the novels of 1924, and, though these may not live more than a few years they are worthy of study as affording an insight into what pleases contemporary readers. Furthermore, the author of one of them must be claimed as specially expert in his craft." Our correspondent then gives two examples of the sort of thing which he finds objectionable. In the first a wife reports her probable pregnancy in the following words: "By the way, this is my second no go." The second example describes a man and a woman who have met for the first time and are talking about satirical writers, when he says to her: "They must always write about women rather in the spirit of unclean-minded undergraduates who are very upset at not having physically enjoyed their first woman as much as was to be expected." There is no doubt whatever about the nastiness of the second example, and we find it also not a very probable remark for anyone to make. But the first phrase, surely, might be employed between decent married friends. The writer of the letter is a well-known authority on mental disease, and he suggests that if complete lack of reticence is allowed to novelists, the publisher of scientific literature, dealing, for example, with psycho-analytical research, might be advised to escape liability for prosecution by calling his production a modern novel.

Like our correspondent, we regret the prurient indiscretions which mark a good many works of fiction; we are not referring to the selected "best-sellers," which are not mentioned in the letter by name and have not been identified by ourselves. But

¹ Results of Nerve Anastomosis, Brit. Med. Jour., August 30th, 1924.

² Treatment of Paralysis of Recurrent Laryngeal Nerve by Anastomosis, Annals of Surgery, Feb. 24th, 1924.

³ Siegmund Schumacher: Über den Bau und die mechanische Bedeutung des Bandapparates der Kehlkopfgeelenke, Wien. Klin. Woch., No. 39, 1924.

we should be loth to criticise adversely books, otherwise good, on the score of sporadic indecencies, and equally loth to believe that it is by these indecencies that a large circulation is commanded. Authors may be returning to the frankness of Shakespeare, which is a very different thing from the lewdness of the seventeenth and eighteenth centuries. Modern authors, at any rate, may feel that, if, to illustrate what a certain kind of man or a certain kind of woman would have said or done in certain circumstances, it is necessary to be coarse, then the coarseness must occur, the nineteenth century taboo of frankness being disregarded. We cannot believe that to write with persistent indecency would bring about pleasant results to a venal author and a complacent publisher with any regularity, such as is indicated by the term "best-seller," and there is an immoral reason for this view, in addition to better reasons. Indecency in writing or speaking depends upon unexpectedness for the amount of amusement which it causes—and therefore for the amount of charm which it must be allowed to possess for the imperfect humanity which constitutes "best-buyers." A habit of reticence is necessary for the full effect of coarseness, and to-day, at any rate, no one would read the works of Ned Ward for amusement. The objection from a literary point of view to indecent allusions and coarse language is valid when the offensiveness is deliberately introduced to prove the freedom from prejudice of the author, and does not occur because truth demands the garniture of dirt or blasphemy.

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj. R. K. White retires on ret'd. pay and is granted the rank of Lt.-Col.

V. P. Ellis to be temp. Lt. whilst empl'd. as a Dental Surg.

TERRITORIAL ARMY.

Maj. (Prov.) A. F. Hewat and Maj. (Prov.) A. J. Brown are confirmed in their rank.

Capt. T. W. S. Hills to be Maj.

2nd Lt. W. A. Ramsay (late R. Scots) to be Lt.

Charles C. P. Anning to be Lt.

Supernumerary for Service with the O.T.C.—Maj. P. H. Mitchiner to be Lt.-Col. and to command the Medical Unit of the University of London O.T.C.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt. Capt. (Prov.) A. Massey, from the Active List, to be Lt.

ROYAL AIR FORCE.

Flight Lt. C. McC. Jones is transferred to the Reserve, Class D.2.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 24TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely—small-pox, 156; scarlet fever, 1757; diphtheria, 1077; enteric fever, 57; pneumonia, 1477; puerperal fever, 51; cerebro-spinal fever, 15; acute poliomyelitis, 6; encephalitis lethargica, 53; dysentery, 9; ophthalmia neonatorum, 99. There were no cases of cholera, plague, or typhus fever notified during the week.

The number of small-pox cases showed an increase of nine over the number for the preceding week. Twenty-two cases were notified from Derbyshire, 30 from Notts, and 69 from Yorks, N. Riding (Middlesbrough C.B., 65).

Deaths.—In the aggregate of great towns, including London, there were 7 deaths from enteric fever, none from small-pox, 15 from scarlet fever, 50 from diphtheria, 62 from measles, and 202 from influenza, as compared with 195, 142, 124, and 100 in the four preceding weeks. In London itself the deaths from diphtheria numbered 17 and from whooping-cough 43.

INDEX TO "THE LANCET," Vol. II., 1924.

THE Index and Title-page to Vol. II., 1924, which was completed with the issue of Dec. 27th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CIX.—THE TREATMENT OF TWO CHRONIC SKIN DISEASES.

I.—CHRONIC ECZEMA.

ALMOST every skin affection may become chronic, but probably the two which occur most readily to our minds when we speak of a chronic skin disease are chronic eczema and chronic acne. The term chronic eczema may cover a large field, and it is proposed to take some common clinical types and consider the methods appropriate for their treatment.

Types of Chronic Eczema.

One of the most characteristic forms of chronic eczema is that met with in children from a few years of age upwards towards adult life. The common history of such a case is that the patient has suffered from eczema since infancy—at first the usual form of "infantile eczema," with mask like distribution on the face and perhaps patches of eczema also upon the limbs and trunk. The eczema, instead of clearing up under treatment or disappearing spontaneously, as it does sometimes at the age of about 2 years, has continued into later childhood, has become less pronounced upon the face and more extensive and persistent upon the limbs and trunk, and especially behind the knees and at the bends of the elbows, though seldom confined to these areas. There may be periods of weeks or of months when the eczema is comparatively though not completely well, alternating with periods when the eczematous areas become red and weeping and more intensely itchy, so that the child is seen to be constantly scratching them. In most cases the skin behind the knees and at the bends of the elbows and at other parts where there is eczema becomes infiltrated and thickened, or, in dermatological language, lichenified by constant scratching. Such children are often thin and have a worried expression from want of tranquillity and of sleep, and they not infrequently suffer from asthma. The pathogenesis of such cases need not be discussed here, but suffice it to say that it is seldom that they can be cured by dieting, by internal medication, or by measures taken to improve the general health. Such means may help to advance the cure, but they are generally of little avail without careful attention to local treatment.

Another common type of chronic eczema is that seen in adults which frequently begins as an occupational eczema upon the fingers and hands and sometimes also upon the forearms. Such occupational eczemas are of common occurrence in those who work with dyes, chemicals (such as photographic chemicals), acids, French polish, formalin, flour, sugar, packing materials, certain woods, strong alkaline soaps, and in dusty occupations generally. Frequently the eruption disappears if the patient discontinues his work for a time, but sometimes it continues with obstinacy for months or even for years, although the patient may have abandoned the occupation which induced it. Then, too, the eruption may appear upon other parts in the form of patches of eczema upon the arms and legs and sometimes upon the trunk—the clinical type known as "patchy eczema."

In persons who have none of these occupations this chronic eczema of the hands and the patchy eczema of the limbs and trunk may sometimes be seen, and it is often attributed to some internal cause; but usually on careful inquiry it will be found that the chronic eczema had its origin, perhaps months or years ago, so that the incident has been forgotten, in a dermatitis,

the result of some local irritant. Contact with a poisonous plant or weed, use of a strong soap, of a patent ointment, prolonged use of sulphur ointment, the application of tincture of iodine, or in various other ways—all these may form the starting-point of eczematous conditions.

Acute Localised Dermatitis the Origin of Chronic Eczema.

The important point is that the more closely we inquire into the origin of these chronic eczemas the more do we find that they have their origin in some more acute localised dermatitis. The dermatitis once established, the skin becomes hypersensitive to any form of local irritant, and this hypersensitiveness extends to other parts so that the eczema appears elsewhere. Here again, as in the chronic eczema of children, it is the scratching which is mainly responsible for the continuance of the eczema, though mere friction of the clothes, too frequent bathing, excessive use of soap and friction with the towel will serve to keep up the eczema. It may happen that a chronic eczema will sometimes get well during a change of diet or under other altered conditions of living, such as residence in a new locality. But other cases under similar changed conditions will not improve, and it seems impossible to lay down definite rules whereby cases of chronic eczema may be cured by dieting or other internal or general treatment.

Management of a Case.

For the majority of cases of chronic eczema the keynote to successful treatment is protection from local irritants and careful attention to local treatments. The first rule in the treatment of chronic eczemas is to avoid the intermittent contact with water, so that as far as possible the patient should wash the unaffected parts without getting into a bath. The affected areas must be continuously protected by some soothing application. One of the most generally useful is a modified Lassar's paste—i.e., Lassar's paste without salicylic acid—thus: R. *Zinci oxidi*, oz. $\frac{1}{2}$; *pulv. amyli*, oz. $\frac{1}{2}$; *vaseline*, oz. 1. The paste should be spread upon small pieces of butter-muslin or upon small sections of white open-weave bandage—lint is too thick and too heating—and the spread pieces applied like a plaster. Over this is placed the thinnest possible layer of wool and a bandage of light material. This dressing is changed twice in the 24 hours, and at each change the old paste is very gently wiped off with olive oil before applying a fresh piece of spread muslin. It is convenient to keep a number of pieces ready spread in a tin box so that they are at hand when the dressing is changed. For extensive eczemas, or where the eczema is in positions as the face, the buttocks, or the back, this method can be only conveniently employed if the patient is kept in bed; but for eczema on the limbs or hands it may be used while the patient is getting about. It is of importance that the treatment should not be relaxed until the affected areas are completely well, or scratching or other irritation will soon bring it back. When progress is slow, in spite of careful protection in this way, more rapid improvement may be brought about by the addition of lenigallol to the paste or by the use of White's tar ointment. The prescription for the lenigallol paste would be: *Lenigallol*, gr. 10–20; *zinci oxidi*, dr. 2; *pulv. amyli*, dr. 2; *vaseline*, oz. $\frac{1}{2}$. For the tar ointment: *Crude coal-tar*, dr. 1; *oxide of zinc*, dr. 1 (mix together and add starch powder, oz. 1, *vaseline*, oz. 1, previously mixed). Each of these should be employed in the same manner as the zinc and starch paste.

Obstinate Cases.—In some cases of obstinate eczema, especially in the infantile eczema, in chronic eczema in children, and in the patchy eczema in adults, rapid improvement may be obtained by the use of a tar paint, as follows: *Crude coal-tar*, oz. 1; *colloidion*, oz. 1; *acetone*, oz. 1. The tar paint is applied with a brush and allowed to dry on and the painting

repeated every two or three days. In some cases of chronic eczema between the more acute attacks it will be found useful to apply without any bandaging a zinc and starch paste, or a zinc ointment (dr. 1 of zinc oxide to oz. 1 of vaseline), with the addition to either of small quantities of one or other of the following drugs, or with a combination of two or more: *Oleum cadini*, min. 5 to oz. 1 of ointment or paste; *acid. salicyl.*, gr. 5; *acid. pyrogall.*, gr. 1–2; *chrysarobin*, gr. 1–5 to the ounce.

Still another local application of the protective type which suits some cases of chronic eczema is a zinc cream made, not in the usual way with olive oil, but with linseed oil, thus: *Zinci oxidi*, dr. $\frac{1}{2}$; *olei lini*, oz. 1; *aq. calcis*, oz. 1. This forms a flexible protective coating which is not greasy and need not be removed at each fresh application.

X Rays.

In spite of diligent endeavours to cure a chronic eczema by one or other of these measures we may fail to eradicate the disease and to prevent fresh outbreaks. The use of the term "chronic eczema" is in itself an indication of the difficulty experienced in curing these cases. But fortunately we have now another resource, the use of X rays. X ray treatment may be employed in all forms of eczema, and in chronic eczemas it is often invaluable. It is used with perfect safety provided the dosage is correct. In the treatment of eczema the best results are obtained with small doses, but even these must be carefully measured and, above all, carefully spaced in point of time, so that we do not get an overdose by an accumulation of small doses. The most generally useful dose for the treatment of eczema is one-third of a full dose, a full dose meaning the largest dose that may be given without subsequent damage to the skin. This corresponds with the depilation dose used in the treatment of ringworm of the scalp and with the B tint of the Sabouraud pastille. If fractions of the full dose are being given they are ordered as $\frac{1}{5}$ B Sabouraud or $\frac{1}{4}$ B, $\frac{1}{3}$ B, $\frac{1}{2}$ B, $\frac{2}{3}$ B, $\frac{4}{5}$ B, $\frac{5}{6}$ B, and 1 B for the full dose. The important rule is that a full dose must not be repeated in less than one month, and that in the course of one month a greater number of fractions than will produce one full dose should not be given. A $\frac{1}{5}$ B dose may with safety be repeated at intervals of seven days, a $\frac{1}{3}$ B dose at intervals of ten days, a $\frac{1}{2}$ B dose at intervals of two weeks, and these doses may be continued at these or longer intervals as long as required. If the intervals between the doses are diminished $\frac{1}{5}$ B doses should not be repeated more than five times, $\frac{1}{3}$ B more than three times, $\frac{1}{2}$ B more than twice, that is not after one full dose has been administered.

In treating a chronic eczema by X rays each of the affected areas may be given a dose of $\frac{1}{3}$ B. If this, after a few days or a week, effects great improvement, as it generally does, a further dose of $\frac{1}{3}$ B may be postponed for several weeks or longer. Where there is much infiltration and thickening the $\frac{1}{3}$ B dose may be repeated at intervals of ten days. In some cases it will be found that better results are obtained by giving a series of $\frac{1}{5}$ B doses at intervals of from one to three days until a maximum of five $\frac{1}{5}$ doses have been given. But then an interval of a month must be allowed before giving any more. It may happen in obstinate, though perhaps not very pronounced, chronic eczemas that the eruption will be cleared up by a single application of $\frac{1}{3}$ B. Among hospital patients X ray applications are of particular value in chronic occupational eczemas of the hands. It is even possible in many instances to cure the eczema while the patient is still following his occupation by means of properly spaced applications of small doses of X rays over considerable periods.

Physician for Diseases of the Skin, St. Bartholomew's Hospital, London.

Special Articles.

ON THE INTER-RELATIONS OF ALASTRIM OR PARA-SMALLPOX, VARIOLA, AND VACCINIA FROM THE CLINICAL STANDPOINT.

By A. F. CAMERON, M.D., C.M. EDIN., D.P.H. CAMB.,
MEDICAL SUPERINTENDENT, RIVER HOSPITALS AND AMBULANCE
SERVICE FOR SMALL-POX AND FEVER, METROPOLITAN
ASYLUMS BOARD.

AN infectious disease has been prevalent in this country for several years of which the diagnosis still gives rise to dispute. The disease certainly belongs to the class of infections of which small-pox is the most important member, and the majority of observers will, I believe, acknowledge that the origin of the dispute is found in the facts that the disease in question is not only very obviously a close relation of small-pox (more closely related to small-pox than is varicella, for example), but also in many of its examples resembles small-pox so closely in clinical features that differentiation from small-pox at the bedside presents very great if not insuperable difficulty.

For these reasons opinion is divided. On the one hand, it is maintained that the disease in question has no features which are inconsistent with small-pox in many of its mild and discrete examples. On the other hand, there are observers who point to the low grade of severity of the disease, a feature which carries with it naturally a very low case mortality, or in some outbreaks a complete absence of fatality, and also to the persistence of this epidemic characteristic throughout lengthy periods of observation. These observers maintain that this feature, and particularly the established fact that it persists for long periods of observation, is sufficient in itself, and in spite of the clinical resemblance to small-pox, to mark off the disease in question from small-pox as formerly understood in this country. In consequence of this opinion they consider that it is now expedient, for the purpose of scientific accuracy, to adopt a special name for the disease which will indicate the relationship to small-pox as well as the divergence from that disease, and there are some who advocate a relaxation of the administrative measures now applied to the disease in question, in order to make the procedure less rigid than the procedure which follows the occurrence of small-pox.

It is necessary to state for the sake of clearness that there are some observers who are of opinion that the clinical features of the disease in question *can* be distinguished from those of small-pox, but it will be evident by reference to most of the many descriptions of the disease which have been published, that there is no single clinical feature which is common to all cases of the disease in question, and also is not found in many of the cases of acknowledged small-pox of mild and discrete type. By acknowledged small-pox is meant cases of that disease which are of mild and discrete type, and give rise to or occur in sequence of transmission from cases which are "classical" in their onset, in their course, and in their severity. It is also important to note that if attention is concentrated on the purely objective features of the disease in question—that is to say, on the features which are recognised by the medical attendant as the direct result of his personal inspection, to the exclusion of the subjective features of the attack, that is to say, the history of his illness in its onset and course as supplied by the patient and his friends—it will be found that the difficulty of differentiating the disease from mild and discrete small-pox is enhanced to a very remarkable degree.

It may therefore be stated that we are concerned with an epidemic disease which resembles acknowledged small-pox very closely, in fact so closely that

many of its examples cannot be separated from small-pox at the bedside; but as time goes on and generation after generation of cases come under observation, it is noted that all the cases have been and continue to be of a low grade of severity, and this epidemiological feature is considered by some observers to be inconsistent with former and present experience of the epidemic history of acknowledged small-pox.

Is it possible to explain the course of events in this country, and the peculiarity of the epidemic history of the disease in question on the assumption that the disease is small-pox and nothing else?

The Meaning and Estimation of Severity in Small-pox.

It is acknowledged that epidemics of small-pox, as of other infectious diseases, vary in severity. Variation in epidemic severity is brought about by variation in severity of attack, and means that the average severity of attack in one epidemic is greater or less than the average severity of attack in another. Severity of attack in infectious disease is determined by the interaction of several factors, of which the most important are the virulence, the toxicity, or the toxin-producing power of the infecting organism on the one hand, and on the other the degree of immunity of the individual attacked. Both factors are variable, and our knowledge of the conditions which produce variation is very imperfect. The influence of each factor on severity of attack cannot be estimated separately, but only in conjunction by the result of their interaction which is seen in the clinical phenomena of toxæmia. But since the influence of the one factor is positive and of the other negative in its effect, it is evident that the presence of toxæmia is an indication of virulence or toxicity in the infecting organism, and for practical purposes it may be assumed that severity in the clinical feature increases with increase in toxic power of the infecting agent.

Many years ago Ricketts gave his attention to the question of how the severity of an attack of small-pox may be most satisfactorily estimated for statistical purposes, and he set out the following classification which was published in the Annual Report of the Metropolitan Asylums Board for 1907 where it may be found. This classification is still in use in the metropolitan small-pox hospitals:—

1. Hæmorrhagic or toxic small-pox.
2. Small-pox confluent on the face in the papular or vesicular stage.
3. Small-pox confluent on the face at the time of maturation (sixth day of rash).
4. Discrete small-pox with more than 500 pocks on the face.
5. Discrete small-pox with more than 100, but not more than 500 pocks on the face.
6. Discrete small-pox with not more than 100 pocks on the face.

There is one defect in this classification which Ricketts recognised and stated. The defect is that there is no common denominator for all the classes. I believe that Ricketts recognised that toxic power—that is, virulence—is the most important factor in the production of severity, but rejected it as a basis for classification because it did not allow of sufficiently accurate estimation. Therefore, in his first class, which he called hæmorrhagic or toxic small-pox, in the greater part of his second class, and perhaps in a minority of his third class, severity and result of attack are associated with the primary fever of the disease—i.e., with the toxæmia of small-pox and not with the focal rash and its effects. These cases die, and they die as the direct result of the toxæmia, of which the main determining factor is the toxicity or the virulence of the infecting organism.

On the other hand, in the greater part of Ricketts' third class and in his fourth, fifth, and sixth classes, severity of attack is related to the severity of the focal rash and is determined by the amount of suppuration. Since the face is the chief absorptive area, it is determined by the amount of suppuration on the face, and this is estimated by a count of the number of

lesions on the face when outcrop is completed, because enumeration of the lesions is the best available means of determining the amount of suppuration. The upper limit of severity of these cases is "confluent small-pox," early confluent in Class 2 and later confluent in Class 3, and among the latter are found those cases in which the tendency to fatality initiated by the toxæmia of the disease is made certainly effective by the toxæmia of the process of maturation. In regard to prognosis, Ricketts recognised that a pre-existing immunity might make its presence felt at any stage of the attack with a consequent improvement in expectation of life for the patient.

There is no doubt that the best clinical basis of a classification of severity of attack is severity of toxæmia, and it seems to be unnecessary to reject this basis because a very accurate measurement of toxæmia cannot be made. The majority of observers will agree that the most important contributory cause of fatality resulting from infectious disease is the toxæmia of the disease, and that this clinical condition makes itself evident in the onset and gives evidence of its strength by the nature of the onset and the effect of the onset on the patient. Using toxæmia as a basis, cases of small-pox as seen in the "classical" outbreak, may be classified as follows:—

1. Severe toxic with death before the focal rash has erupted fully.
2. Severe toxic continuing without intermission followed by a confluent focal rash and death in the early stage of that rash.
3. Severe toxic with intermission followed by a confluent focal rash and death in the late stages of that rash or recovery after severe fever of maturation.
4. Moderate toxic with intermission followed by discrete focal rash and slight fever of maturation.
5. Mild toxic with intermission followed by very discrete focal rash and no fever of maturation.

It is to be noted that the presence of a degree of immunity may bring about the transference of cases which are apparently candidates for the second class to the third class or even to the fourth or fifth class. These transferences are commonplaces among any series of cases of acknowledged small-pox. It is also matter of experience that the more severe is the onset, the primary fever, the toxæmia, by whatever name the condition may be described, the more apt is the succeeding focal rash to be severe, and it may be accepted that fulminant small-pox—that is to say, the attack which exhibits in the severity of the pain, in the complete prostration of the patient, and in its widespread purpuric rash, the most evident signs of a severe toxæmia—would have produced, if death had not supervened, a focal rash which would have become completely confluent before vesiculation was fully established. It may also be accepted that the mild onset, the mild primary fever, the mild toxæmia is not followed by a severe focal rash. In such a case it may happen that the focal rash, by the number of its units in the very early stage, gives promise of considerable severity. But experience shows that this promise is not fulfilled on account perhaps of early resolution of a proportion of the units or by the later intervention of the effect of the presence of a degree of immunity against the disease.

Death from small-pox—that is to say, death due to the toxæmia of the disease—supervenes in the cases in Class 1 and in those in Class 2. Toxæmia is not the prime cause of fatality in the cases falling in Class 3 or in Classes 4 and 5. If the primary fever, or as I should prefer to say the signs of toxæmia, remit and more notably, of course, if they intermit, the expectation of life for the patient takes a steep upward trend, although he may succumb later in his illness to the overwhelming effects of a focal rash which has become confluent in the process of maturation. Death in this type of case is to be regarded as death from a sequela of the disease rather than death from the disease itself, as Ricketts has pointed out. It follows that the outbreak of small-pox from which the type of case belonging to Classes 1 and 2, and also

a proportion of the cases falling in Class 3, are removed, will have no case-mortality directly attributable to the disease, and that the case-mortality in such an outbreak will be low and mainly due to accidental individual conditions. It is the cases in these classes which show the clinical evidence of high toxicity of the infecting organism. There seems to be no reason to demand that this evidence of high toxicity should invariably be shown by the organism of small-pox. Long-continued mild infection is recognised to be a feature of other forms of infectious disease. Nor does there seem to be any reason to doubt that the removal of toxicity from the infecting agent may reach a point where fatality from the disease ceases.

The Relation of Vaccinia to Small-pox.

The great majority of observers are agreed that the disease in question and vaccinia are mutually protective. Vaccinia and acknowledged small-pox are also mutually protective. Therefore the disease in question and small-pox stand in identical immunological relationship with vaccinia.

Vaccinia is an inoculated disease of which the "matter" is derived from the pustules of acknowledged small-pox. It is unnecessary to enter fully into the methods of attenuation of the virus which are used in the manufacture of the anti-smallpox vaccine. It is sufficient to note that the result of the process is an undoubted attenuation of the virus, and that this attenuation, once it has been established, cannot be removed by any artificial means at present available. That is to say, the anti-smallpox vaccine cannot by any artificial means be sufficiently enhanced in virulence to enable it to give rise to an attack of inoculated small-pox. The occasional cases which are described as generalised vaccinia may be discounted in this argument on account of their very great rarity. Even in former days when arm-to-arm vaccination was the practice, it was found that repeated transmission tended towards further attenuation and not towards enhanced virulence. It is not outside the bounds of possibility that a similar attenuation in the virus of small-pox may occur by natural processes, that this natural attenuation may not reach the high degree attained by artificial means in the manufacture of anti-smallpox vaccine—that is to say, that natural attenuation may go only so far as a reduction in the power of the virus to produce a septicæmic infection and not so far as the complete removal of that power which is brought about in the laboratory; and as in the case of anti-smallpox vaccine, that the particular strain of virus which has become naturally attenuated may fail to recover virulence. A discussion of possible reasons for this failure seems to be too speculative to be of practical value.

This assumption is consistent with the experience that the epidemic power of small-pox apparently tends to wear itself out in an affected area, a recession which seems not to be accounted for sufficiently by the immunising effects of an increased use of vaccinia. The suggestion will also explain the observed contrast between the low case-mortality in the latter period of epidemic small-pox and the high case-mortality of the rising epidemic wave, which was noted in the London outbreak of 1901-02-03. The assumption has also the support of analogy in the case of the organism of diphtheria, an organism which apparently tends to a gradual loss of virulence and of which it is stated: "there is no evidence that a totally non-virulent strain can be made to show even a slight accession of virulence by any artificial means."¹

Therefore, (1) on account of the very close resemblance of the clinical features of the disease in question to those of mild and discrete small-pox; (2) from an analysis of the factors which contribute to the production of severity of attack in small-pox; (3) from the consideration of the immunological relations of the disease in question and of those of small-pox;

¹ Diphtheria. Medical Research Council. Chap. ix., p. 322.

and (4) from the analogy presented by the known properties and action of anti-smallpox vaccine; it seems reasonable to suggest that small-pox, produced by an attenuated virus, is sufficient to account for the peculiarity in the epidemic history of this disease and that there seems to be no need to postulate another disease of the small-pox type or of the nature of a hybrid between variola and varicella or even a sub-variety of small-pox, in order to explain the course of events in this country and the epidemiological features upon which so much emphasis has been laid by some observers.

Questions of administration are really outside the scope of this memorandum, but it is necessary to refer to them on account of the implication contained in the opinion on diagnosis which has been expressed by the observers previously referred to. The argument advanced by these observers seems to take the following line:—

Let it be granted that this disease is a very close relative of small-pox or even that it is a true small-pox produced by a strain of virus of degraded virulence, the facts remain that the incapacitating effect of the illness is very slight and the case-mortality very low, so low that on occasion it disappears completely. This mild disease has now existed in this country for several years with very little, if any, alteration in its features. But we are still employing the full weight of our heavy anti-smallpox artillery against this epidemic disease which is more nearly comparable to chicken-pox than to small-pox in the disturbance which it causes. Is it not now time, for the sake of the credit of medical science and also for the sake of a saving in public expenditure, to recognise officially the obvious difference between this epidemic disease and our old "classical" outbreak of small-pox? Is it not probable that the continued use of vaccinia in our attempts to prevent the spread of this disease will bring still further discredit on small-pox prophylaxis and render the administrative procedure which is necessary for the control of "classical" small-pox even more difficult of application than it is at present? because it has been found in several cases that vaccinia has a greater incapacitating effect than the disease against which we are using it.

From the point of view of clinical medicine which must remain the only safe basis of administrative procedure, after all has been said that can be said in favour of epidemiological distinctions, this argument is obviously unsound. From the point of view of efficient administration, no adequate reason is apparent for refraining from stating frankly that the disease in question is small-pox and nothing else, so far as our present professional knowledge goes. There is no discredit attached to an imperfect knowledge of medical science, but discredit is very apt to follow attempts to conceal our ignorance such as the invention of a new name for a condition with features so elusive that they very frequently conceal themselves completely. It is conceded that the use of anti-smallpox vaccine and the isolation of cases of the disease in question will prevent the spread of the disease just as they prevent the spread of acknowledged small-pox, and notwithstanding the severe result which may occasionally follow the inoculation of vaccinia, it must not be forgotten that vaccinia is not a transmissible disease. In suggesting a relaxation of procedure, no allowance is made for the admitted and grave possibility of the coexistence of a virulent strain of small-pox with this strain of degraded virulence, or for the possible importation during the prevalence of this mild disease, of a strain of high toxicity of which the first results to be observed may be cases of a very mild type. If it is assumed that a natural attenuation of virus will continue unimpaired under all conditions, the assumption is too dangerous for use as a basis of administrative action. We are ignorant of the conditions which brought about the attenuation and we are equally ignorant of the conditions which may reinforce virulence. There is

one important administrative question to which no answer seems to be forthcoming from any of the supporters of relaxation of procedure. What is the grade of severity or what is the upper limit of case-mortality which will justify a relaxation of our anti-smallpox procedure in dealing with this disease? What is the grade of severity or what is the figure of case-mortality beyond which relaxation should cease?

LEAGUE OF NATIONS HEALTH ORGANISATION:

A VISIT OF FOREIGN PUBLIC HEALTH OFFICIALS.

UNDER the auspices of the Health Organisation of the League of Nations a further visit to Great Britain of public health officials from different countries commenced on Monday last. This is the third occasion on which foreign officials have studied British public health services on the spot, and the following are the representatives of the various States attending the Conference:—

Denmark.—Dr. A. Metz, County M.O.H., Holbaek, Denmark.

Estonia.—Prof. K. Schlossmann, Director of Bacteriological Laboratories, University of Tartu (Dorpat).

France.—Dr. L. M. Pilleboue, M.O.H., Department de l'Herault, France. Dr. E. Robin, M.O.H., city of Nantes, France.

Germany.—Dr. Walter Kloninger, M.O.H., Adenau, District of Coblenz, Germany. Dr. Lenz, M.O.H., District Bartenstein, East Prussia, Germany.

Greece.—Dr. T. Katsoyannis, Director, Section of Infectious Diseases, Ministry of Health, Athens, Greece.

Holland.—Dr. M. D. Horst, M.O.H., city of Leyden, Holland.

Italy.—Dr. G. Hoffer, Port M.O.H., Venice, Italy.

Jugo-Slavia.—Dr. M. Jakovljevitich, District M.O.H., Djeveljija, Serbia.

Norway.—Dr. Ivar Tosti, Asst. M.O.H., city of Oslo, Norway.

Poland.—Dr. Jan Bogdanovicz, M.O. (M. and C.W.), Ministry of Labour, Warsaw, Poland.

Russia.—Dr. E. Braguine, M.O., Ministry of Health, Moscow, Russia.

United States of America.—Dr. S. L. Christian, U.S.A. Public Health Service.

Canada.—Dr. Wodehouse, Secretary, National Tuberculosis Association of Canada.

The party was received by the Society of Medical Officers of Health, words of welcome being spoken by Prof. H. R. Kenwood and Lieut.-Col. S. P. James, of the Ministry of Health. Formal presentations later took place at the Ministry of Health to Mr. Neville Chamberlain, after which Sir George Newman addressed the party on English public health administration. The representatives of foreign countries then divided into four groups for the study of public health administration and practice in urban and rural areas outside London, as follows:—

Group A.: Middlesex (Dr. John Tate) and Willesden (Dr. G. F. Buchan).—Dr. Pilleboue (France), Prof. Schlossmann (Estonia), Dr. Hoffer (Italy), Dr. Braguine (Russia), Dr. Wodehouse (Canada).

Group B.: Yorks W.R. (Dr. J. R. Kaye) and Leeds (Dr. J. J. Jervis).—Dr. Christian (U.S.A.), Dr. Metz (Denmark), Dr. Tosti (Norway), Dr. Kloninger (Germany), Dr. Bogdanovicz (Poland).

Group C.: Staffordshire (Dr. W. D. Carruthers) and Wolverhampton (Dr. R. H. H. Jolly).—Dr. M. D. Horst (Holland), Dr. Robin (France), Dr. Jakovljevitich (Jugo-Slavia), Dr. Lenz (Germany), Dr. Katsoyannis (Greece).

The whole party will reassemble in London on or about March 8th, for the study of Health Schemes and Institutions in the Metropolis. On March 24th they will leave England for the closing Conference to be held at Geneva on March 25th and three following days.

These interchanges have been rendered possible by the financial assistance of the Rockefeller Foundation.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

THE PROVISION OF MEDICAL BENEFIT.

*Evidence by Mr. Brock and Dr. Smith Whitaker
(continued).*

Formal Complaints.

(App. C. 40-49.) Each Insurance Committee is required to set up three standing subcommittees for the investigation of complaints. The Medical Service Subcommittee is the one which deals with complaints against doctors, the Pharmaceutical Service Subcommittee hears complaints against chemists, and the Joint Services Subcommittee deals with cases in which both doctors and chemists are involved. Each of these bodies is constituted on the same principles, and it is sufficient here to refer to the Medical Service Subcommittee. This has an equal number of members appointed by the representatives of insured persons and doctors respectively and a chairman appointed by the neutral members of the Committee. The procedure of this body is formal and its hearings are judicial in character. The Committee find facts and make recommendations and the Insurance Committee come to a decision on these facts. From their decision there is a right of appeal to the Minister.

(Q. 1014.) There are, of course, a good many cases which do not reach the stage of a formal complaint. These are settled at the offices of the Insurance Committee when it is merely a matter of clearing up a misunderstanding. The number of formal complaints investigated in England and Wales is roughly 1700. At a later stage in the evidence Mr. Brock gave the following particulars:—

(Q. 1307-9.) Out of a total of 1646 cases the doctor was acquitted, or the case was not substantiated, in 647, and there were 999 proved cases. Out of the 999, grant was withheld in 31½ per cent.; the doctor received a warning in 51½ per cent.; and in the remaining 17 per cent. he was required to refund to the insured person the amount that the insured person had spent in obtaining the services of another doctor.

About 40 per cent. of the complaints were, it will be seen, not justified, and of those cases (647 in number) in which the doctor was acquitted 100 were allegations of neglect, 250 of inadequate treatment, 105 of fee charging, 142 of irregular certification, and 50 of a miscellaneous nature. There is a tendency for the number of complaint cases to increase. As to this, the witness said that he did not think that this implied that the service is less satisfactory. (Q. 1018.) It really means that insured persons are much more alive to the rights which they enjoy under the Regulations; and also that for a time after the war committees naturally had to take a rather more lenient view because of the number of practitioners who were returning from military service and who suddenly found themselves accepting obligations the full extent of which they perhaps had very little opportunity of studying.

Monetary Penalties.

(App. C. 54.) The reference above to the withholding of grant means that the Minister has power to withhold part of a doctor's remuneration where the service provided has been unsatisfactory; he may do this with or without a recommendation from the Insurance Committee. Before any such sum is withheld, the doctor or chemist is afforded an opportunity of making representations orally or in writing to officers of the Ministry. The number of cases in

England in recent years in which monetary penalties have been imposed on practitioners is given below:—

Year.	No. of cases.	Amount withheld.
1920	18 ..	£583
1921	59 ..	£855
1922	115 ..	£2181
1923	132 ..	£3131

The cases themselves are classified as follows:—

Neglect in treatment (failure or refusal to visit, unsatisfactory treatment, &c.)	103
Charging fees	66
Irregularities in certification	53
Failure to keep records	39
Failure to make returns where cases are sent to referees	28
Various other classes	35

The amounts of grant withheld usually vary from £1 to £100. In five cases the amounts have been higher and in one of these £1000 was withheld.

The £1000 Case.

This case, which appears from the evidence to be quite an isolated case, occurred in 1923 and has attracted a good deal of comment in the general as well as the medical press. (Q. 1022.) It concerned a firm of two practitioners practising in a self-contained area. It was a fairly large village sufficiently far from the nearest town to make it difficult for any other doctors to practise in that district. Both these practitioners had been making a charge to their insured patients expressed as a charge for the bottle of medicine, but in fact, according to the local custom, it was a charge which also covered treatment. This had gone on for a considerable time. The Insurance Committee made representations for the removal of the practitioners from the panel. A Committee of Inquiry reported to the Minister, who, said the official witness—

while he took the view that the facts established would be quite sufficient to justify the removal of those two doctors from the Medical List, also felt that there were special circumstances that would warrant him in imposing a less grave penalty. I think he was principally influenced by the fact that if those two practitioners had been removed, there were no other doctors practising in the area who could have undertaken the care of their insured patients. . . . In ordinary circumstances where a breach of the doctor's contract is so grave as to justify a penalty of anything like that sum it has been generally felt that the proper way to deal with it is by removal from the list and not by the imposition of anything in the nature of a fine. It was only the very special local circumstances of this case which led the Minister to deal with it differently.

Learning by Experience.

(Q. 1202, 1203.) The witnesses were asked whether it was not necessary for doctors to know a great deal about the machinery of the Act. They replied that some doctors learn it and some do not. Those who do learn usually learn by experience as members of Panel Committees or by the experience they have had as defendants in cases in which there are complaints.

As to young doctors coming on the panel for the first time, it was thought that the best way of becoming acquainted with the Regulations would be for a man to go as an assistant to a general practitioner and get actual experience of practice. It was suggested by a member of the Commission that a short course of lectures on the machinery of the Act might be a useful preparation to panel practice, but the witnesses seemed to entertain doubts as to the value of this proposal.

Depreciating the Panel Service.

(Q. 1275.) In some cases insured persons deliberately ask to be treated as private patients.

Q. Can you suggest any reason why an insured person who is already paying a doctor should ask that same doctor to treat him or her as a private patient?—A. I think it is partly the result of the unfortunate speeches of some people rather prominent in the Friendly Society world who repeatedly depreciate the insurance medical service. That is bound to create an impression in the minds of some insured people that if they come as private patients they may in some way or other be better treated.

* In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247-8); The Provision of Medical Benefit (Feb. 7th, pp. 301-3). References to the official statement which has been issued as an appendix in four sections are given thus: Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

(Q. 1234-7.) As to differences in waiting-room accommodation for insured and private patients, the witnesses said there was no evidence of such cases. There may be one place of waiting for the well-to-do and another for those who are not so well off, but not a distinction between insured as such and non-insured as such.

Removal from the Panel.

(App. C. 56.) The removal of a doctor from the panel is usually preceded by representations from the Insurance Committee that his continuance on the panel would be prejudicial to the efficiency of the Insurance service. The case is then investigated by an Inquiry Committee appointed by the Minister, consisting of a barrister or solicitor as chairman and two doctors, who hold a public inquiry and report to the Minister their findings of fact and inferences. The Minister then decides in the light of their report whether the name of the doctor is to be removed from the list or not. A doctor, it appears, may terminate his agreement by giving the prescribed notice at any time, but the action of the Insurance Committee in this respect is limited to securing by means of representations made to the Minister that an inquiry shall be held with a view to the removal of the practitioner from the list. (Q. 1021.) In England and Wales 32 doctors have been removed since the Acts came into operation and in addition eight have been allowed to resign to avoid removal, so that in effect 40 have been removed. (Q. 1029.) This does not include those persons who, having been removed from the Medical Register by the General Medical Council, have been automatically taken off the panel.

The following questions were asked as regards reinstatement:—

(Q. 1025, 1026.) What is the position of a doctor when he has been removed from the panel? Can he ever get back again?—A. Yes, it is open to him at any time to apply for restoration. Q. Must he apply formally?—A. He must apply formally, and before a decision is reached it is usual to consult the Insurance Committee and the Panel Committee of the district in which he previously practised. He would also be required to produce evidence as to his conduct in the meantime from medical men in the area in which he had been working.

With regard to criticism of the power of the Minister to remove doctors from the list, the witnesses said:—

(Q. 1033.) We have gone into that on several occasions in discussion with the Insurance Acts Committee of the British Medical Association, and the root of the matter, as they recognised frankly the last time we went into it with them, is the statutory provision.... The criticism, carefully analysed, has always turned out to be a criticism of the statutory provision which gave the Minister power to remove a man. It has been contended by some doctors that such a matter should be dealt with by the General Medical Council, or that there should be some machinery for referring the matter to the High Court. But we have always had to answer that that is a question of legislation.

Asked whether the service could be administered on the lines on which it has been established without such a controlling power, the witnesses said:—

(Q. 1034.) The only method of getting rid of a doctor who is not working satisfactorily is the power of the Minister to remove.... We have to recognise that the criterion of the Act in this respect is not like that of the Medical Act, removal on the ground of infamous conduct in a professional respect, or anything of the kind. The power of the Minister to remove depends on his being satisfied that the practitioner's conduct is prejudicial to the efficiency of the service, so that the power is essentially one for controlling the proper standard of the service. It is difficult to see how a power of that kind could be exercised satisfactorily except by someone responsible to Parliament, which, of course, would not apply to the General Medical Council or to the High Court.

The commonest causes for removal from the panel have been persistent or very gross negligence. Another cause has been drunkenness, and then there have been two or three cases in which a practitioner was quite intractable; he would not carry out any of the Regulations, some, perhaps, not important in

themselves, but without which the system could not be carried on. But the majority of cases have been for negligence in treatment.

(To be continued.)

INFECTIOUS DISEASES ABROAD.

Acute Poliomyelitis.—New Zealand is at present experiencing a sharp outbreak of this disease. The weekly notifications began to increase during December, 1924. The number of cases notified in the first week of January this year was 19, in the second week 30, in the third week 60, in the fourth week 58, and in the week ending Feb. 2nd 88. A report from Wellington, dated Jan. 16th, states that the Health Department has prohibited the attendance of all children under 16 years of age at schools, theatres, cinemas, and other public places throughout the North Island. In all other countries the few outbreaks which were reported during 1924 subsided before the end of the year. They included a very severe outbreak in Iceland with an incidence of about two cases per 1000 inhabitants and a case-fatality, in cases showing definite paralysis, of 37 per cent. Elsewhere the chief outbreaks reported during 1924 were, as usual, in Scandinavia, Great Britain, and the United States. The following statement, which gives the available notifications from certain countries during the last two years, shows that in most of them the disease was more prevalent in 1924 than in the previous year. No reported outbreak, however, was comparable in extent and severity with the epidemics of 1911, 1912, and 1916.

	Cases.	
	1923.	1924.
Sweden	313	685
Denmark	75	152*
Finland	47	51
France	175	216*
England and Wales ..	587	760

United States (27 States) ..	2458	3000†
Australia	137	227*

* To Nov. 30th.

† Approximate cases to Dec. 6th.

Influenza.—In the statistics available from various foreign countries and cities for the month of January this year there is no indication of a recrudescence of influenza on the continent of Europe corresponding to that which is now affecting certain areas in Great Britain. The deaths notified as being due to influenza during the first three weeks of January in Paris, Antwerp, Stockholm, Copenhagen, and Amsterdam were fewer than those notified during the same period of last year.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Scottish Courts and a Medical Report.

MANY people may think that a mountain has grown out of a molehill in the discussions held recently in the courts in Scotland with reference to a medical report upon an injured workman in connexion with a claim under the Workmen's Compensation Acts. Neither party was in doubt about the accident, nor about the original injuries, nor about the liability of the employers, all of which were admitted, and compensation was paid for two years on the basis of total incapacity. Then the employers—or those behind them—presented the view that the workman was all right again and fit for his ordinary duty, and as the workman denied this they claimed a reference to a medical referee. An essential step towards such reference is that the employers shall present a medical report from their own doctor, and until that is presented the reference to a medical referee will not be ordered, and so the compensation

must continue to be paid. The employers had all this fully in view, and therefore when they applied in the county court for a remit to the medical referee they tabled their own medical report. It is over this report that the fight has been waged, and in the Court of Appeal in Scotland, by a majority, the decision was given that what the employers' doctor wrote cannot be received as a medical report, and therefore the employers' application is thrown out. This judgment reverses the decisions of the registrar of the county court and of the county court judge, and, as has been said, there was a dissenting opinion in the Court of Appeal.

The report was in the following terms: "Having examined A.B. on 11th October, 1924, I certify him as fit for work, and the reason for my opinion is, had he begun light work when told to, he would now be fit for full work." Whatever may be said against this document it certainly has the cardinal virtue of brevity. Nothing could be more concise. Apparently, however, the doctor has fallen between two stools, and has come to grief on the dilemma of too great and too little compression. If it may be premised that in the opening clause of the report "work" means "full work," then, so taking it, what is said against the report in substance comes to this, that, on the one hand, the first clause certifies that the man is fit for full work, and, on the other hand, the remainder of the report certifies exactly the contrary, because—so the argument proceeds—it says that he *would* now be fit for full work *if* he had done something which he did not do, which appears to imply, or definitely to assert and certify, that the man is *not* fit for full work. But of course there is another view—namely, that the opening clause does not refer to full work, but to light work, which would lead to diminution of the compensation and not its total stoppage. But this middle view found no judicial support. On the contrary, the dissenting judge thought that, although the language was lacking in lucidity, "there is not the slightest doubt as to what the doctor really meant"—namely, that, whether the man is now able for full work, or for light work, or for no work, his condition, whatever it may be, is no longer due to the accident, but arises from his not undertaking light work at the time when he was told to do so. This is certainly a good deal to be read into, or out of, the report. There is much to be said for the dissenting judge's view that it is extremely to be regretted that such technical questions under the Workmen's Compensation Acts should be brought before the Supreme Courts. Meantime it may be useful to note, what, of course, everyone knows already, that "such a report should be clear and consistent; it should be its own interpreter."

Royal Medical Society of Edinburgh: Annual Dinner.

The annual dinner of the Society was held in the hall of the Royal College of Physicians of Edinburgh on Feb. 5th. Dr. T. Drummond Shiels, M.P., presided over a company numbering about 120. The guest of the evening was Mr. Alexander Miles, and among those present were: Lord Provost Sir William Sleigh, Prof. G. Lovell Gulland, President of the Royal College of Physicians; Sir Harold Stiles, President of the Royal College of Surgeons, Sir Robert Philip, the Hon. Lord Constable, the Very Rev. Prof. Paterson, D.D.; and Surgeon Commander P. L. Crosbie, R.N. Mr. Miles, proposing the toast of "The Royal Medical Society of Edinburgh," said that it was, and always had been, a students' society. It was well authenticated, he continued, that the Society was founded in August, 1734, about 190 years ago, and that it was the oldest medical society in the Kingdom. Describing the formation of the Society, Mr. Miles said that six students, after spending a social evening together in a tavern, agreed to meet once a fortnight in their respective lodgings, where it was arranged that a

dissertation in English or in Latin on some medical subject should be read by one of them and discussed by the others. This band of six was soon joined by one whom they were always proud to count among the founders of the society—no less than the celebrated William Cullen—and he, perhaps more than any man, served to make the foundations sure. They must keep in mind that at the time the society was founded medical opinion was in a state of flux. Medical practice had for long been based on the doctrines of speculative philosophers, of whom Boerhaave, of Leyden, was the chief apostle. But a school was arising, directed by Hoffmann, which sought to replace these abstract theories by knowledge based upon observed facts. Cullen was one of the leaders of this school, and there is no doubt he exerted a powerful influence upon his fellow-members, stimulating them to think and to observe for themselves, and to question on every point the voice of authority. It was well recognised, he said, by medical historians that it was mainly through the influence of the Edinburgh school that the doctrines of Hoffmann and the method of the experimental system came to dominate. The Society after three years having found its feet, the members resolved to form themselves into a definitely constituted body, and they drew up a constitution and adopted the name of the Medical Society in 1737. In 1778 it became incorporated under Royal Charter, and the Society now had one of the finest medical libraries in the country, containing well over 30,000 volumes.

The membership of the Society embraced the names of men who had made medical history in this country for nearly two centuries. Among the most distinguished members, in medicine, he mentioned Andrew Duncan, Richard Bright, Marshall Hall, Robert Christison, Douglas MacLagan, and Byrom Bramwell. In surgery there were the Bells, Robert Liston, William Fergusson, James Syme, and the greatest of all, Joseph Lister; and in obstetrics, James Young Simpson, A. R. Simpson, and Halliday Croom. A great many of their members had also become distinguished outside of medicine. There were Mark Akenside, the poet; Oliver Goldsmith; Mungo Park, the explorer; Sir Henry Holland, the traveller; Sir Gilbert Blane, who introduced lime-juice into the Navy; Sir Charles Hastings, the founder of the British Medical Association; Robert Finlay; Thomas Addis Emmet, the Irish patriot; and Charles Darwin.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Medical Candidates for Dail Eireann.

WITHIN the next few weeks bye-elections will take place in no less than nine constituencies in the Irish Free State. In two of these the candidate for the Government Party will be a medical man. In Co. Cavan Dr. J. J. O'Reilly has been selected, and will be opposed by a Republican and a representative of the Farmers' Party. For the South City Division of Dublin, the Government candidate is Mr. Thomas Hennessy, F.R.C.S.I., who will be opposed by a Republican and a Labour candidate. The Government Party could not have selected a candidate more acceptable to the profession than Dr. Hennessy. He is thoroughly familiar with medical problems and with all questions affecting the health of the country. He has, moreover, a personality and character which have gained him the trust of everyone who has had dealings with him. The South City Division of Dublin has a large number of resident medical practitioners, and a strong medical committee is being formed to assist Dr. Hennessy's candidature. Medical voters will be asked to sink political differences for the moment so as to ensure the return of a representative medical man.

Public Health Administration.

In the Senate recently Mr. P. Kenny, a Senator who always shows an informed interest in health affairs, proposed an amendment to the Local Government Bill, to the effect that a public health council should be set up to advise the Minister, the constitution of the council to be: Eight persons representing boards of health, four representing councils of county boroughs, two representing persons insured under the National Health Insurance Acts, three medical practitioners, one dentist, one veterinary surgeon, two representatives of registered nurses, and two representatives of midwives. They should all be appointed by the Minister, who should be *ex officio* a member of the council. The amendment also provided for payment of travelling expenses, subsistence allowance, and reasonable compensation for loss of remunerative time. The amendment was supported by Mr. O'Farrell, a Labour Senator, who pointed out that in questions of sanitation, and measures for the prevention of disease, Ireland was much behind most progressive countries. Opposition came from the Minister on the ground that such a council would interfere with direct Ministerial responsibility to Parliament. On a division the amendment was defeated by 23 votes to 10. Mr. Kenny left himself open to criticism on the ground of the unwieldy constitution of his proposed council. A body supposed to represent expert sanitary opinion, on which nurses and midwives have a larger representation than medical practitioners, is not easy to defend. That some such council, however, if properly constituted, would be of service to the health of Ireland under present conditions can hardly be doubted.

Housing Conditions in Dublin.

Dr. Brian Crichton gave an address recently to the Dublin Rotary Club dealing with the effect of the housing conditions in Dublin on infant life and health. He pointed out that whereas 50 persons per acre was a normal distribution of a city population, in one ward in Dublin there were 130 per acre, and in another 117 per acre. The death-rate of children in Dublin was nearly double that of London. He mentioned also the difficulty of obtaining pure food for children, and stated that the penalties imposed for selling dirty or impure milk were quite inadequate. Little has been done in the past ten years to improve housing conditions in Dublin, and even ten years ago they constituted a grave danger to the public health. President Cosgrave made the announcement a few days ago that in Dublin in the past few years 940 houses had been erected, or were in course of erection, presumably by Government or with Government help. But this number, useful as it is, can hardly make up for those that have become uninhabitable by the lapse of time, and the general housing accommodation will be even worse than it was ten years ago. It is true that something is being done also by private initiative, and the Rev. D. H. Hall, a clergyman of a poor parish who has done much to promote housing for the poor, recently announced that he had been offered £250,000 at 2 per cent. for his housing scheme, provided certain conditions were fulfilled.

Medical Referees to the National Health Insurance Commission.

The medical referees appointed to act under the National Health Insurance Commission are Drs. J. J. A. Gannon, F.R.C.P.I., P. Magner, and J. A. Cusack. The Commission has issued to medical certifiers a brief pamphlet explaining the duties of the referees. Their services are at the disposal both of medical certifiers and of approved societies. A medical certifier who is in doubt as to the continued incapacity of an insured person whom he has hitherto certified as incapable of work, can make application for the opinion of a referee. The opinion of the latter will be communicated both to the certifier and to

the approved society. Similarly, an approved society in doubt as to the incapacity of a member who is in receipt of sickness or disablement benefit may refer the member for examination to a medical referee. It will also be open to approved societies to refer an insured person admittedly incapable of work who has been in receipt of sickness or disablement benefit for a prolonged period, and in regard to whom the society thinks it desirable that a second medical opinion should be obtained. The function of the referee is to be purely advisory, and neither the certifier nor the society will be bound by the opinion of the referee. The Free State has been apportioned into three districts, in regard to each of which a referee will function. Ordinarily, the insured person will attend for examination at a fixed centre, but in exceptional circumstances an insured person may be examined at his own home.

Royal College of Physicians of Ireland: Honorary Fellowship Conferred on Sir Humphry Rolleston.

On Feb. 7th Sir Humphry Rolleston, President of the Royal College of Physicians of London, was admitted to the Honorary Fellowship of the Royal College of Physicians of Ireland. The President, Sir William Thompson, was in the chair and handed the new Fellow his certificate. Sir Humphry Rolleston then gave an address on "Individual Links Between the Colleges of London and Ireland." He stated that in the 80 years from 1836 to 1916 no less than 28 Fellows of the London College had been admitted to the Fellowship of the Irish College. He referred to several physicians who had associations with both Colleges, among others, Sir William Petty, Sir Edward Barry, Anthony Pelham, and Thomas Brooke. A vote of thanks to Sir Humphry Rolleston was proposed by Dr. Walter Smith, Senior Fellow of the College, and seconded by Sir John Moore. In the evening Sir Humphry Rolleston was present at a Term Dinner of the College.

Fellowships in Sanitary Science.

When the Local Government Bill, at present before the Oireachtas, becomes law, it will be the duty of the county board of health in each county to appoint a medical officer of health. As up to the present there is almost no expert sanitary work done in Ireland, there will be a difficulty in finding trained and suitable candidates. It is satisfactory, therefore, to find that some help is to be given by the Rockefeller Foundation. An official statement just issued by the Department of Local Government and Public Health states that:—

The Department recognises the difficulty that will arise in finding suitable persons to fill the important position of medical officer of health in each county. A number of doctors possess diplomas in sanitary science, public health, and State medicine, but have no opportunity of obtaining experience in general public health administration. The Minister and staff discussed this difficulty with the representatives of the Rockefeller Foundation. Three travelling Fellowships have, therefore, been offered, and when the Bill becomes law opportunity will be given to all qualified persons to submit their names. A committee consisting of medical experts and others to select for fellowship the best qualified and most suitable persons from amongst the applicants will then be set up.

It is further stated that the Fellowships will entail a sojourn in the United States of about eight months. Besides full travelling expenses, the Foundation will pay matriculation, instruction, and other university fees, and a payment monthly is also provided for, while full opportunity for study will be provided at hospitals, laboratories, and specialised institutions. Preference will be given to applicants under 35 years of age. The Fellows must bind themselves to accept appointments as county medical officers of health on their return to Ireland. The assistance given thus by the Rockefeller Foundation will be valuable, but a guarantee of adequate remuneration for the county medical officer of health is necessary if good candidates are to be attracted.

Correspondence.

"Audi alteram partem."

SMALL-POX OR "PARA-SMALLPOX."

To the Editor of THE LANCET.

SIR,—Dr. R. P. Garrow's able and interesting article in THE LANCET of Jan. 31st raises an issue of the greatest practical importance. He contends (with Prof. Jorge) that the ultra-mild small-pox which has prevailed in this country during the last few years is not true small-pox but a separate and distinct disease closely allied to it. If this contention is right our whole administrative machinery for dealing with this disease, which is based on the belief that it is true small-pox, would need to be radically revised. To continue to take the elaborate and costly precautions which we are at present taking would be unnecessary, and, indeed, unjustifiable. It is therefore necessary to scrutinise Dr. Garrow's arguments closely.

At the outset it must be admitted that there is nothing inherently impossible in his proposition. The remarkable constancy with which the present strain of small-pox in this country (or of "alastrim" or "amaas" abroad) maintains its abnormally low virulence and continues to "breed true" lends colour to it. Mere diminution in virulence, however, is hardly sufficient in itself to justify us in postulating a new species of disease, though if such altered virulence prove to be permanent we may, I think, claim that we are at least dealing with a new variety. Dr. Garrow, however, contends that there are definite clinical differences between small-pox and "para-smallpox," which he describes in detail. Here, I think, he goes rather further than the facts justify. What he really does is to draw a picture of the milder example of his "para-smallpox" and compare it with the classical description of small-pox as given in text-books. Of course, the two pictures are very different. It is unfortunate that Dr. Garrow's experience of small-pox other than "para-smallpox" has been, as he himself admits, rather limited. Otherwise I think he would have realised that the text-book pictures of the disease are taken from well-marked and severe cases in order to emphasise the salient features, and hence tend to be overdrawn. Let me take some of Dr. Garrow's points of difference seriatim.

1. *Onset*.—This, he says, in "para-smallpox," is "gradual," whereas in classical small-pox, of course, it is sudden. Personally, I cannot agree that it is gradual, but as the term is purely relative, and there are no means of measuring it, it is not much good discussing it. Then he says that no case in his series gave the classical onset of small-pox with rigor, vomiting, lumbo-sacral pain, and rapid prostration. Yet he admits that some of his cases had shivering, nausea, vomiting, abdominal pain, and backache. Although not prostrated, the "para-smallpox" patient, he tells us, usually "lies down." I suggest that in "para-smallpox" the prodromal symptoms are not infrequently quite as severe as in undoubted small-pox. The following are taken from notes made by me personally amongst the first 14 cases I investigated at Gloucester.

CASE 4.—Aged 23. Very severe pain in back and head; vomiting; stayed in bed three days.

CASE 7.—Aged 19. Pains in back and head, "terribly sick." Eruption on sixth day.

CASE 8.—Aged 18. Pain in back; nausea, very feverish; stayed in bed three days. Eruption on fifth day.

CASE 10.—Aged 11. Very ill for one night. Delirious; vomiting. In bed for three days. Eruption extremely scanty—less than six spots altogether—appeared on seventh day.

CASE 12.—Aged 12. Headache, backache, vomiting, light-headed; in bed for two days. Eruption on third day.

CASE 14.—Aged 21. Slight backache; retching; in bed on and off for nearly a week. Eruption on eighth day (later notes, when seen in hospital). Eruption profuse, coherent on face, thick; discrete on arms; very large pustules.

2. *The Pause*.—The feature of "para-smallpox" on which Dr. Garrow lays most stress is that which he calls "the pause"—i.e., the interval between the cessation of the prodromal symptoms and the appearance of the eruption. I admit that the occurrence of this interval was a feature which struck me in the Gloucester cases, and it is a point which must be taken into consideration. This pause arises owing to the delay which occurs in the appearance of the eruption and the consequent drawing out of the prodromal period. This is shown by the figures given by Dr. Garrow. My own figures for Gloucester cases may be worth quoting also. I personally investigated 144 cases at Gloucester, but in 19 cases definite dates could not be obtained. In 15 cases no prodromal symptoms were noticed; in other words, the prodromal period was absent. Of the remaining 110 cases the eruption appeared as follows:—

Day of eruption..	1st.	2nd.	3rd.	4th.	5th.	6th.	7th.	8th.
Number of cases..	—	11	20	49	22	21	5	2

In classical small-pox the prodromal stage is supposed only rarely to extend to five or more days. This, then, seems a definite point of distinction, *unless* it can be explained as a result of the reduced virulence.

3. *The Eruption*.—Dr. Garrow says the eruption is "not so shotty" as in classical small-pox. I wonder on what comparison Dr. Garrow bases this assertion? Nothing is so difficult to measure as the degree of shottiness. He also says that the lesions are "more rapid in their evolution through the various stages" and that the "scabs and crusts" of classical small-pox are replaced in para-smallpox by what he terms "amber beads." "Amber beads" is quite an intriguing term, certainly more attractive than "scabs and crusts," but I suggest that the modification he describes is not much more than the phenomenon referred to in classical small-pox as the process of "aborting." I would prefer to say that the eruption in "para-smallpox" tends to "abort" rather than to run its full course, but the phenomenon is not in any way specific.

4. *Secondary Fever*.—Dr. Garrow rightly states that the amount of secondary fever and constitutional disturbance in para-smallpox is usually very slight or entirely absent, though where the pustules are large and deeply seated in the skin (as they sometimes are) there is slight secondary fever. The question is, is the secondary fever less than we should expect in view of the scantiness of the eruption? I am inclined to agree that it is so. Also I have been impressed with the rarity of secondary septic infection of the skin in para-smallpox in cases where the eruption was profuse. But then, is this a specific difference or is it part of the phenomenon of lessened virulence?

5. *Other Features*.—Prodromal rashes are certainly very rare with the present strain of small-pox, but this again may be due to the lessened virulence. Eye complications are quite as bad as we should expect in view of the general benignity of "para-smallpox."

Conclusion.

In conclusion, it must be remembered that different epidemics of any disease will vary in certain minor particulars and sometimes in more important ones; also that many diseases have become modified by lapse of time or change of environment. Especially is this true of virulence and fatality. Small-pox, as it has existed in the provinces for the past few years, certainly presents a very different picture from what it did 30 years ago or even as it sometimes still does to-day. Moreover, these differences have been maintained and it has continued to breed true. The type therefore appears to have become fixed. The question is: Are we to regard it (a) as the same disease, or (b) as a separate disease, sui generis, distinguishable clinically, as Dr. Garrow contends, from small-pox on the one hand and from chicken-pox on the other?

Personally, I would reject both these views and seek a compromise. I think that Dr. Garrow goes too far. I do not regard it as a distinct disease, nor do I believe that it is possible to diagnose individual cases of the present ultra-mild small-pox from ordinary small-pox. I prefer to regard it as a sub-variety of small-pox, sufficiently distinct epidemiologically to justify some distinction in terminology.

I am not enamoured of the term "para-smallpox" because the analogy with paratyphoid is misleading. The term would, of course, have been quite justified if "para-smallpox" reacted to vaccinia differently from ordinary small-pox. Personally, I prefer the suggestion made recently in THE LANCET by Dr. R. W. Jameson, that we should use the terms variola "major" and "minor" in order to make the necessary distinction, and I could wish that the Ministry of Health would give official sanction to this, at the same time issuing a memorandum indicating the modifications in administrative procedure which they would approve in epidemics which were found to be only variola minor.

I am, Sir, yours faithfully,
Leicester, Feb. 4th, 1925. C. KILLICK MILLARD.

SMALL-POX AND ALASTRIM, VARIOLA MAJOR AND MINOR.

To the Editor of THE LANCET.

SIR,—Your correspondents for the most part seem to concentrate on the individual case to the exclusion of the general view of an epidemic as a whole, and so doing, lose the view of the wood because of the trees.

The small-pox epidemics of 1897 and 1923 at Gloucester were so different that a large section of the public there considered them distinct diseases. The council committee responsible for small-pox expenditure, though they were only fulfilling the behests of Government, lost their seats at the next election.

The official inability to distinguish between variola major and minor, both of which bred true, is a serious matter; for disregard of the present advice leads to nothing with variola minor, but should variola major later break out in the same place, it might well spread to a considerable extent before the community realised that this time medical advice was in accordance with the facts. Variola minor confers only an evanescent immunity to vaccination; by analogy the same may well be true as regards the protection it confers against variola major, while we know variola major confers a long period of immunity against itself, vaccination, and variola minor. The official view being that all small-pox is the same, what advice is to be officially tendered to persons who have had small-pox within five years if again exposed to infection? To me the protection conferred by vaccination lasting longer against variola minor than variola major is a point of some diagnostic value, and the Glasgow figures for variola major in 1921 and those of the C.M.O.'s annual report of 1923 are of some interest when compared.

Drs. Millard and Garrow both show that the majority attitude is no longer tenable, and I would like, Sir, to reiterate my view that an investigation of the whole subject is very necessary; also that as vaccination has not been officially investigated for 30 years it would be a great pity were a partial inquiry to be granted as the result of lay pressure, the profession remaining supine in the matter.

I am, Sir, yours faithfully,
ROBERT W. JAMESON.
West Wickham, Kent, Feb. 3rd, 1925.

EXTENSOR PLANTAR RESPONSE IN POISONING BY MORPHINE.

To the Editor of THE LANCET.

SIR,—Dr. G. M. Kendall's observation of a bilateral extensor response in a case of morphine poisoning (THE LANCET, Feb. 7th, p. 308) is not without precedent. Personally I recorded a similar

experience in 1914 (*Practitioner*, vol. xciii., p. 330), and another case is certified by Sir James Purves-Stewart (*Diagnosis of Nervous Diseases*, sixth edition, p. 97). In the paper quoted above my purpose was to show that coma per se, that is apart from organic disease of the central nervous system, may be an influence sufficient to determine an extensor response, and as such a response has now been recorded after quite a number of narcotic drugs and other soporific agents the argument advanced in my paper would appear to be strengthened. Such an explanation is surely much more probable than the hypothesis that each agent exercises some specific action on the nervous system. There are other experiences which go to support the same conclusion, though these can hardly be set forth within the compass of a brief letter.

As a general proposition it can, I think, be argued that any agency which disturbs the normal functional relation between the cerebral cortex and the motor cells of the spinal cord may be accompanied by a plantar extensor response, and among such agencies coma, however produced, obviously has a place. The practical outcome of such a doctrine is that, given a comatose patient with extensor responses, it is not necessary to conclude that such a combination inevitably means an organic brain lesion; it may mean narcotic poisoning.

I am, Sir, yours faithfully,
Feb. 9th, 1925. C. O. HAWTHORNE.

TREATMENT OF APPENDICITIS.

To the Editor of THE LANCET.

SIR,—Mr. Rendle Short's interesting lectures on appendicitis (THE LANCET, Jan. 31st and Feb. 7th) afford several points for reflection and some also for criticism. On one matter in particular, the treatment of post-operative ileus, my own experience and some interest in the subject have led me to form opinions so different from his that I venture to express my views. Mr. Rendle Short is no half-hearted advocate of the administration of powerful purgatives and peristaltic stimulants in the treatment of ileus after operation for appendicular peritonitis, and no doubt there are many experienced surgeons who share this view.

If we consider the state of affairs inside the abdominal cavity during the first few days after operation for diffuse peritonitis, we will agree that ileus, in any marked degree, is due to inability of the lower small intestine to transmit its contents owing to acute inflammation of the bowel walls and also to fixation of intestinal coils by deposits of plastic lymph. Now we may treat this condition on the assumption that there is still some kick (pardon the phrase) in the intestinal walls if only a sufficiently powerful impetus be given to them to elicit a response; if the assumption is justified, and sometimes it is, then a bowel action follows, flatus is passed, and the patient will probably weather the storm. But what of the not inconsiderable number of cases in which this assumption proves false? It will be found in these that the condition has been hurried on into one of full-blown acute intestinal obstruction. I contend that it is a much better plan, safer and more likely to be followed by success, to treat the patient in the belief that the obstruction is due to transient causes and will clear up as the peritonitis subsides if we can tide him through this period; to promote this policy the intestines must be kept at rest till there is evidence of a return of function, and meanwhile the patient's vitality must be maintained. In practice, then, we should cease to administer any food or fluid by mouth (chewing of fresh fruit may be allowed) and instead institute continuous subcutaneous infusion of saline solution; empty and wash out the stomach by means of the stomach tube—the stomach will be found to contain intestinal contents often in great quantity, which emphasises the futility of relying on drinks by mouth for the patient's sustenance; administer small doses of

morphia and 12 to 24 hours later a simple enema will usually enable the patient to pass flatus and faecal material; the enema should be repeated in 12 hours' time.

There are few things more striking in surgical work than the rapid improvement in the patient's condition, appearance, and subjective sensations which follows this treatment. As I have pointed out elsewhere, post-operative ileus can be prevented to a great extent by taking certain precautions at the operation for appendicitis and by care in the immediate after-treatment. Purgation before operation for acute appendicitis has long been recognised as a grave mistake, and I believe it to be so after operation, at least in the severe cases with diffuse peritonitis.—I am, Sir, yours faithfully,

Manchester, Feb. 8th, 1925.

H. H. RAYNER.

AIR-EMBOLISM FOLLOWING URETHROSCOPY.

To the Editor of THE LANCET.

SIR,—Prof. Andrew Fullerton's letter is important as it draws attention to the fact that accidents during aero-urethroscopy are more frequent than have been recorded. Most will agree that simply on account of this urethroscopic examination should not be abandoned, but the question arises, Is aero-distension essential in every case? I have elsewhere stated (*Practitioner*, July, 1924) that it is advisable for diagnostic purposes first to examine the urethra without distension, for many pathological conditions are thus better observed. Hyperæmia, slight infiltration, excessive secretion, granular and patulous states of the mucous membrane vanish when the urethra is distended with air, so I personally reserve aero-dilations for obscure cases and for operative purposes. If this practice is followed no operator need fear air embolism.

I am, Sir, yours faithfully,

Harley-street, W., Feb. 3rd, 1925.

M. W. BROWDY.

THE ACIDIC VALUE OF THE URINE IN SKIN AND OTHER MANIFESTATIONS.

To the Editor of THE LANCET.

SIR,—With reference to Dr. Doble's article on the above in your issue of Feb. 7th, I should like to state that it has been my routine practice for many years past to examine the urine of my private patients by a long series of tests including the reaction to litmus.

In by far the greater proportion of cases of acne and so-called "seborrhœic" dermatitis the reaction has been found to be either very mildly acid to litmus or amphoteric, though on rare occasions either a high acidity or a high alkalinity has been met. I have inquired of my biochemical friends as to the validity of the simple litmus test and have been informed that it is satisfactory, any error in the litmus test lying rather on the side of its indicating a higher degree of acidity than is actually present.

When Drs. Barber and Semon published their researches on the acidity of the urine associated with "seborrhœic" dermatitis during the war I endeavoured to control their work in this country, but was unable to obtain confirmatory results, as I believe was the case with others who attempted control work. I therefore came to the conclusion that what they had described was a state of things due to the special conditions in the field and was not to be found in ordinary civilian life. In Dr. Doble's case I am on firmer ground, as he is presumably dealing with a sample of the population similar to that which I have investigated, and here I am in a position to state definitely that the urine of most cases of acne and "seborrhœic" dermatitis as seen by me in large numbers is not notably high in acidity or alkalinity.—I am, Sir, yours faithfully,

Harley-street, W., Feb. 9th.

ARTHUR WHITFIELD.

BREAST DISEASE AND THE *DEMODEX FOLLICULORUM*.

To the Editor of THE LANCET.

SIR,—The article by Dr. Helen Chambers and Miss Millicent Somerset in THE LANCET of Jan. 24th under the above title, opens up a new idea for the workers in comparative medicine, and it may interest your readers to see by the accompanying photograph

Bull puppy severely affected with follicular mange.

(for which I am indebted to the late Prof. Mettam, of the Royal Veterinary College of Ireland) the widespread form which the demodex parasite often takes in the skin of the dog. The authors of the paper might have added the horse to their list of domesticated animals which can be infected, but it is in the dog that the veterinarian most commonly meets with this form of mange. It is by no means an uncommon affection and is well recognised by the canine practitioner, and, indeed, too, by many owners and breeders. In animals I have never read or heard of it as associated with cancer.

It is met with in all breeds and is more common in the young dog than the old one, the incidence of age in cancer being the reverse. Although I am not aware that especial attention has, up to the present, been paid to the point as to whether the demodex parasite can be microscopically demonstrated as common in (or around) the nipples, I know from experience that the mammæ of animals are not a usual spot for visible evidence of its lodgment. It may come on any other part of the body, and it is especially troublesome to treat around the lips and eyelids, particularly in breeds (such as the bull-dog, bloodhound, or spaniel) whose skin in those regions is loose and pendulous.

To assert decisively that it is incurable, even in the dog, is scarcely quite correct; although in most instances the trouble and length of time which it takes influences the owner to decide upon the painless destruction of the patient. Some four or five months as a minimum is usually asked for, and a variety of external preparations are used, one of the most effectual being a weak solution of chloride of zinc, applied daily after squeezing out the contents of every pustule which may be visible.

I am, Sir, yours faithfully,

FREDERICK HOBDAV, F.R.C.V.S.

Section of Comparative Medicine, Royal Society of Medicine, Wimpole-street, W.,
Feb. 4th, 1925.

REX v. BATEMAN.

To the Editor of THE LANCET.

SIR,—You are no doubt aware that this appeal came on for hearing to-day at the High Court, when the same was allowed and the conviction quashed. Judgment however was reserved, but will be given in due course. Dr. Bateman was of course discharged.

Our client wishes us to thank you for the great financial and moral support which you have given him, and which has enabled him to bring this appeal to such a successful conclusion. It is extremely doubtful whether we could have brought sufficient weight to support the appeal, without the interest which you have taken throughout the proceedings, and in support of the medical profession generally. We ourselves desire to join in our client's gratitude.

We are, Sir, yours faithfully,
AMERY-PARKES & Co.

66 and 68, Whitcomb-street, Coventry-street,
London, W.C. 2, Feb. 10th, 1925.

Obituary.

SIR GEORGE ANDERSON CRITCHETT, BART., K.C.V.O.,

SURGEON-OCULIST TO THE KING; CONSULTING OPHTHALMIC
SURGEON TO ST. MARY'S HOSPITAL.

WE regret to announce the death of Sir George Anderson Critchett, which occurred at a nursing home on Monday last in the eightieth year of his age, after an operation. He was a hereditary ophthalmologist, for not only could he look back on a career of over 50 years as an ophthalmic surgeon himself, but as successor to a distinguished father, he was a link with the founders of modern ophthalmology. William Bowman, Jonathan Hutchinson, George Lawson, and George Critchett were the great names in the ophthalmic world in the 'sixties and 'seventies of last century, and George Anderson Critchett, the son of the last, was born in the atmosphere of ophthalmology and was approaching manhood at the time when the discovery of the ophthalmoscope produced a renaissance in the study of diseases of the eye. "La réputation d'un père est un lourd fardeau pour le fils." But in the case of Anderson Critchett, great though his father had made the name, he undoubtedly added to its repute, and it is safe to say that few British ophthalmic surgeons were better known in the world.

Born in London in 1845, Anderson Critchett was educated at Harrow, where he gained the prize for English literature, and Caius College, Cambridge, where he captained the College cricket eleven and made many friends, but did not proceed to a medical degree. On leaving Cambridge as a Bachelor of Arts in 1867, he entered the Middlesex Hospital and qualified M.R.C.S. in 1872, later proceeding to the F.R.C.S. Edin. There was a period in his career, however, when it seemed doubtful whether medicine or music would claim him. He possessed a fine baritone voice, a love for the drama, and social qualities which acted together to draw him away from the profession of medicine, but affection for his father and a desire to be of help to him prevailed. He decided to follow in his father's footsteps and accordingly filled junior ophthalmic appointments until he secured election first to the Royal Free Hospital as ophthalmic surgeon and then to St. Mary's Hospital as lecturer on ophthalmic surgery. There followed upon this good start a life of steady professional success. He was appointed ophthalmic surgeon to St. Mary's Hospital in 1881 and rapidly became known both as operator and learned man, and from the beginning his reputation was as high on the continent as in England. It is of interest to note that his first published paper on "Inoculation in Ophthalmic

Practice" was published in a French journal, *Annales d'Oculistique*, in 1877. It was his work at St. Mary's Hospital that finally established his reputation and incidentally built up one of the biggest eye clinics at any of the general hospitals in London, and he was the first to recognise how much he was aided in his work at St. Mary's by the late Henry Juler and how loyally they worked together when a few years later Juler was co-opted as his colleague. His career from now onwards is a simple record of increasing honours accorded to him. He was appointed surgeon-oculist in ordinary to the late King Edward in 1901, in which year he was knighted, being advanced to a baronetcy in 1908.

The public positions held by Sir Anderson Critchett were very numerous. He was at different times President of the Ophthalmological Society, President of the Council of British Ophthalmologists, President of the Ophthalmological Section of the International Congress of Medicine, and President of the International Ophthalmological Congress, in this way repeating an honour which had been bestowed upon his father a generation before. He had been President of the Section of Ophthalmology in the Royal Society of Medicine, and his conduct in the presidential chair on so many occasions never failed to win respect. His polished speaking was especially happy on ceremonial occasions, while his contributions when he intervened in debate were founded on vast clinical experience.

Critchett was also a member of the Société Française d'Ophthalmologie, and certain of his papers were published in the Transactions of that society and simultaneously in THE LANCET. He contributed, as has been said, to the *Annales d'Oculistique* and, of course, to the Transactions of the Ophthalmological Society. From beginning to end his writings were of a practical character. The first paper published in our columns was instigated by the arrival of cocaine. Before the introduction of cocaine, in England at any rate, the majority of ophthalmic surgeons administered an anæsthetic during the operation for extraction of cataract, but Anderson Critchett pointed out that the absence of pain secured by the new agent, though of the greatest possible value, had certain drawbacks, and described his own technique for iridectomy, using the ring-finger to elevate the upper lid, as "Nature's speculum." Thirty years later, in his address to the Seventeenth International Congress of Medicine as President of the Section of Ophthalmology, he described the value of the X rays as an aid to the location of foreign bodies in the eye and its adnexa, and amongst similar new adjuncts to diagnosis mentioned the delicate manometers assisting the surgeon to estimate the tension of the eye. Of other contributions to the technical side of his specialty we may mention his method of employing the cautery in the operation for conical cornea and his advocacy of treating certain cases of lamellar cataract by making an artificial pupil, but he generally preferred to practise well-tried methods rather than to devise new ones. He was never a prolific writer, and to the regret of many of his pupils, much of his teaching, which would have been of great value, is lost for want of recording. For he was a great clinician and unrivalled as an operator. To see Critchett removing a cataract in the heyday of his skill was to see the perfection of operative technique. Never a hurried or purposeless movement was made, and if any untoward complication had to be met, it was faced with the same steady placidity as if it had been foreseen from the first. He had to a very high degree the most valuable capacity of rousing in his patients an implicit feeling of confidence and the equally valuable capacity of creating a feeling of friendship in his colleagues.

During the war he served as ophthalmological surgeon to King Edward VII. Hospital and to King George's Hospital, and in 1919 received the K.C.V.O. His last professional honour reached him as recently as 1924, when he was chosen Master of the Oxford Ophthalmological Congress. Apart from the distinctions which he received from two kings, Critchett

held every honour that it was possible for his colleagues to confer on him. Such a record by itself shows the esteem in which he was held by those best able to judge of his work, an esteem which could only have been earned by the genuineness of character which gave rise to it. To few men has it been given to have such a happy full life; happy in his work, happy in his friendships, and happy beyond expression in his family life, he reached the end of his long term of years without ever growing old.

Sir Anderson Critchett married a daughter of the late C. J. Dunphie, of Rathdowney, Queen's Co., by whom he had two daughters and one son, George Montague, who succeeds him in the title.

THE LATE DR. JOHN FRASER.

In appreciation of the late Dr. John Fraser, Medical Commissioner of the Scottish Board of Control, whose death we announced recently, we have received the following notice from Prof. George M. Robertson, to whom also we are indebted for the portrait of Dr. Fraser. Prof. Robertson writes:—

"News of the death of Dr. John Fraser in the eightieth year of his age, as the result of a fall when alighting from a tramcar, has been received with sorrow over the whole of Scotland, where in his capacity of Deputy Commissioner between the years

difficulty than he in having his recommendations put into effect. These were priceless gifts to one in his position, who was engaged during his term as Commissioner in levelling up the methods of administration and of nursing in the mental hospitals of Scotland. He was interested in the hospitalisation of asylums, in improved methods of nursing both by day and by night, in the nursing of male patients by women, in the abolition of restraint and seclusion, and in the precaution against fire. His genuine sympathy for the patients, his knowledge of their conditions of life, and his kindly manner of treating them, won their affection and confidence. No one appealed to him in vain. He had words of comfort for all which smoothed over their difficulties. He was regarded by them as a real friend."

Dr. Fraser was born in Thornhill, Dumfriesshire, and studied medicine in Edinburgh, where he had a distinguished career as a student, gaining nine medals and graduating with first-class honours in 1870. After holding resident appointments in the Edinburgh Royal Infirmary, he was appointed assistant medical officer to the Fife and Kinross District Asylum at Springfield, Fife. A few years later he was promoted medical superintendent, succeeding Sir John Batty Tuke in this post. Dr. Fraser married a sister of Sir John Batty Tuke, who predeceased him, and he is survived by three sons and two daughters. One of the former is Dr. J. S. Fraser, aural surgeon, Edinburgh.

1877 and 1895 he visited boarded-out patients in every parish. He knew the country so well that he said he could not be placed in any part of it that was unfamiliar to him. In addition, he was on friendly terms with most of the inspectors of poor and medical officers of these parishes. In 1895 he was promoted Commissioner, and retired owing to the age-limit in 1910. Dr. Fraser was an honorary member of the Medico-Psychological Association, and on his retirement from office he was presented with his portrait painted by Mr. Fiddes Watt, R.S.A. Since his retirement he has been much interested in charitable organisations, and especially in the work of the Society for the Prevention of Cruelty to Children. He has led a useful and a good life, which has been characterised by untiring energy and singleness of aim in his work. Above all he has been distinguished by his friendliness, his kindness, and his deep interest in all those persons with whom he came into contact in the discharge of his duties, whether these were officials or patients. His relations with the former were so good and his honesty of purpose so transparent that no official had less

Medical News.

UNIVERSITY OF LONDON: LECTURES AND DEMONSTRATIONS IN MEDICAL HYDROLOGY.—The third annual course at the University of London has been arranged by the Committee for the Study of Medical Hydrology in Great Britain, and will take place from April 27th to May 2nd next, concluding with visits and demonstrations at Buxton and Matlock. Introductory discourses will be given by Dr. John C. Thresh on the Types of Water which Occur in Nature; on Hydro-geology, by Mr. H. Dewey, of H.M. Geological Survey; and on the Capillary Circulation in the Skin by Prof. Barcroft. Dr. Fortescue Fox will deal with the Properties and Actions of Medicinal Waters, the Actions and Uses of Baths, and the Use of Heat in the Treatment of Disease. Applied Hydrology forms the subject of three lectures; by Dr. J. B. Burt on Disorders of Digestion; by Dr. Vincent Coates on Arthritis; and by Dr. Rupert Collins on Neurasthenia. These lectures will be delivered at the University of London, South Kensington. Demonstrations on the Bacteriological, Physiological, and Chemical Analysis of Waters will be given in the Counties' Public Health Laboratories; and by Dr. Leonard Hill at the National Institute for Medical Research on the Effects of Open Air and Sunshine upon the Body. At Buxton there will be brief lectures and demonstrations, both on methods of treatment and of research, given at the bath establishments and at the Mineral Waters Hospital, by local medical men. Full particulars may be obtained from the Hon. Secretary, Hydrology Committee, University Extension Board, University of London, S.W. 7.

The *Introductory Medical Course* for students who have matriculated in the University of London will begin at University College on Monday, March 2nd. Intending students should apply at once and should attend at the College on Monday, March 2nd, at 11 A.M.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On March 2nd a comprehensive three weeks' course in Medicine, Surgery, and Gynaecology will be conducted at the Royal Waterloo Hospital. There will also be demonstrations given by the staff in the wards and out-patients' department. Beginning on March 9th is a four weeks' course in Ophthalmology at the Central London Ophthalmic Hospital. The course is an afternoon one and deals with the more important diseases of the eye. An Operative Surgery class will be held by arrangement. The Chelsea Hospital for Women is arranging a special three weeks' course from March 16th, and the work will embrace the various Gynaecological Affections, and also operations and demonstrations by members of the staff. The Hospital for Diseases of the Chest (Brompton) begins a fortnight's course on March 16th. The course consists of demonstrations, lectures, operations, &c., in all the

departments associated with chest diseases. The Royal Northern Hospital in conjunction with the Royal Chest Hospital is arranging an intensive course in Medicine, Surgery, and the Special Departments from March 23rd to April 4th. Copies of the syllabuses of the above-named courses, together with the Fellowship Bulletin, may be had on application to the Secretary at 1, Wimpole-street, W. 1.

HULL AND A UNIVERSITY COLLEGE.—The Right Hon. T. R. Ferens, of Hull, a P.C. and a former M.P. for East Hull (1905-1918), has written to the Lord Mayor stating that he has set aside £250,000 as a nucleus for founding a University College for Hull. Amongst his other gifts to Hull were £10,000 for the purchase of a site for a new technical college and £60,000 for the erection of a new art gallery.

EPSOM COLLEGE WAR MEMORIAL.—The Bishop of Winchester, the Visitor of the College, will consecrate the nave of the chapel at 3 P.M. on Saturday, Feb. 21st. The total cost of rebuilding the chapel, which work was begun in July, 1923, will be about £11,500, and so far the Council have received contributions amounting to about £9000. Contributors to the War Memorial Fund who wish to be present at the ceremony are requested to apply for a card of admission to the Bursar, Major Walter L. Giffard, The College, Epsom, Surrey.

CHADWICK PUBLIC LECTURES.—On Monday, March 9th, at 8 P.M., in the Inner Temple Hall, Lord Newton will give an address on the Necessity for Legislation with regard to Smoke Abatement. Sir William J. Collins will be in the chair. In May Dr. E. Brumpt, Professor in the Faculty of Medicine at the University of Paris, will give two lectures (in English): (1) How to Conduct an Anti-Malarial Campaign, and (2) the Prophylaxis of Sleeping Sickness. Admission to all Chadwick public lectures is free. Further information may be obtained of the Secretary, Mrs. Aubrey Richardson, O.B.E., at the offices of the Trust, 13, Great George-street, Westminster, S.W. 1.

NORTH-EAST LONDON POST-GRADUATE COLLEGE.—A special post-graduate course covering the work of all the departments of the Prince of Wales's General Hospital, Tottenham, N., begins at 10.30 A.M. on Monday, Feb. 16th, with a demonstration of the graphic method of studying heart disease. It will be continued every day throughout the ensuing fortnight, each week, however, being complete in itself. In the mornings there are to be demonstrations of modern clinical methods, in the afternoons demonstrations of groups of selected cases and clinics in the various departments of the hospital. At 4.30 P.M. each day there will be a special clinical lecture. The opening lecture will be given by Mr. James Sherren on Appendicitis, and all the lectures at this hour will be free to members of the Fellowship of Medicine as well as to members of the College, while the opening lecture will be free to members of the profession. The succeeding lectures of the first week will be on the Home Treatment of Diabetes, by Dr. F. G. Crookshank; on Cancer of the Colon, by Mr. H. W. Carson; on Spinal Anaesthesia, by Dr. C. F. Hadfield; and a lantern lecture, by Mr. J. Howell Evans on Cysts and Cystic Conditions of the Neck. On Saturday, at 11 A.M., Dr. F. Thomson will give at the North-Eastern Fever Hospital, St. Ann's-road, Tottenham, a demonstration of cases illustrating the Early Diagnosis of the Infectious Fevers. Luncheon will be obtainable in the neighbourhood of the hospital, and at 4 P.M. each day tea will be provided. Application for admission to the course should be made to the Secretary of the Fellowship of Medicine (1, Wimpole-street, W. 1) or to the Dean of the College.

LIVERPOOL OPEN-AIR HOSPITAL FOR CHILDREN.—The Countess of Derby on Feb. 5th opened the new administration wing of this hospital situated at Leasowe, near Liverpool. The Liverpool open-air hospital for children suffering from surgical tuberculosis provides accommodation for 260 children, the majority of whom are sent into the hospital crippled. The average duration of treatment is from 18 months to two years. At the ceremony on Feb. 5th the hon. treasurer was able to claim that the working cost of the hospital of £2 per bed per week was the lowest for similar institutions in the Ministry of Health's returns, while the chairman of the medical board announced a percentage of 78.4 of the children discharged during the previous year with the disease quiescent. The new wing has cost some £16,500 to build, of which about £10,000 is still to find. The hospital is run under the aegis of the Liverpool Child Welfare Association, and a feature of "Leasowe" is the admirable after-care system by which all discharged patients are followed up, home conditions reported on, help given, and relapses dealt with at an early date.

Dr. James Hopwood Jeans, F.R.S., secretary of the Royal Society, and Sir William Henry Ellis, G.B.E., have been appointed to be members of the Advisory Council to the Committee of the Privy Council for Scientific and Industrial Research.

GIFT OF SANATORIUM TO DURHAM.—Subject to the approval of the Ministry of Health, the Durham County Council have accepted an offer from the Marquis of Londonderry of Seahall Hall, to be used as a sanatorium for the treatment of tuberculous cases in the county. After suitable alternations the hall would afford accommodation for about 80 patients.

PROBLEM OF THE CRIPPLE.—Mr. M. Fitzmaurice-Kelly addressed the Brighton and Hove Rotary Club on Feb. 4th on the subject of the Problem of the Cripple. Taking the county of Sussex as a whole, Mr. Fitzmaurice-Kelly declared there were some 1500 cripples, and he claimed that if the cases were taken in hand in earliest childhood and treated with the skill which medical and surgical science had now devised, the very great majority of them were curable. He spoke of the system of treatment which had originated in Shropshire and was now being copied in various parts of the country, Wiltshire and Somersetshire, and expressed the opinion that the time was ripe for Sussex to make a move. He suggested that a hospital of 100 beds would meet the county's needs and would probably cost £60,000 or £70,000 to establish, and its running expenses would be about £12,000 to £15,000 a year. He did not think this was beyond the means of the county, but meanwhile he urged the immediate setting up of local clinics in various centres.

MANCHESTER'S £10,000,000 WATER-SUPPLY.—The Waterworks Committee of the Manchester Corporation have recommended the City Council to proceed at once with the Haweswater reservoir scheme for increasing the city's water-supply, which will cost about £10,000,000, and described as the biggest of its kind in the country. It was stipulated when Parliament sanctioned the scheme in 1919 that it should be completed by 1934. The scheme involves the construction of a giant aqueduct nearly 80 miles in length from Haweswater to Manchester, of which 28 miles will be underground. In carrying out the scheme, the lake will require to be raised about 90 feet, its length of two and a quarter miles increased to four miles, and widened by about a quarter of a mile, and its surface increased from 350 to 1000 acres. The raising of the water level by means of a dam will mean the submergence of the hamlet of Mardale, an hotel, several farms, and a parish church. The church it is proposed to remove and erect elsewhere. It is computed that the scheme will give Manchester an additional potential daily supply of 70,000,000 gallons and will ensure the city's water-supply for the next 50 or 60 years. Manchester at present receives 52,000,000 gallons of water a day, and it is calculated officially that at the present rate of increase of demand the existing resources will be exhausted in eight or nine years. The Thirlmere scheme was sanctioned in 1879, and the fourth pipe therefrom was only recently completed. The Thirlmere scheme cost the city £7,000,000.

SUSSEX PROVIDENT SCHEME.—Great progress was made during 1924 by the Sussex Provident Scheme. By the scheme provision is made against the more serious illness requiring hospital treatment or the services of a specialist, to which the National Health Insurance scheme does not apply, and people with incomes up to £350 a year can, by joining into groups or associations, or by registering direct, insure against the most serious possibilities that illness or accident may hold out over the average human being. The scheme saw its inception in 1920, and although it was at first viewed with a certain amount of suspicion there were just over 7000 subscribers to it at the end of 1923, and at the end of 1924 the figure was only a few under 10,000. With the dependents, the total number who stand to benefit is well over 25,000. During 1924 the following amounts, totalling £5520, were paid to the hospitals named for services rendered to subscribers to the scheme:—

Royal Sussex County Hospital, £2806; Royal Alexandra Hospital for Sick Children, £823; New Sussex Hospital, £538; Brighton, Hove and Preston Dispensary, £309; Haywards Heath Hospital, £248; Sussex Maternity and Women's Hospital, £207; Sussex Eye Hospital, £170; Brighton and Hove Provident Dental Hospital, £120; Sussex Throat and Ear Hospital, £76; Uckfield Cottage Hospital, £19; Royal East Sussex Hospital, Hastings, £2; Stephen Ralli Memorial Laboratory, £27; Consultations, £9; Queen's Nurses, £9; refunded for treatment to subscribers at non-co-operating hospitals, £157.

These figures suggest that the anticipations of the founder, Dr. J. F. Gordon Dill, are being fully realised, for they encourage the hope that the scheme is providing a solution for some of the financial problems of the voluntary hospitals.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Feb. 16th.

MEETING OF THE SOCIETY : at 5.30 P.M.

Special Discussion on

Non-specific Disturbances of Health due to Vitamin Deficiency.

Speakers :

Dr. Leonard Williams, Colonel R. McCarrison, Dr. William Cramer, Dr. G. M. Findlay, and others.
(The Meeting may be adjourned at 7 P.M., and resumed at 8.30 P.M.)

Tuesday, Feb. 17th.

PATHOLOGY : at 8.30 P.M.

D. Thomson : Researches on *B. pneumosintes*.

G. M. Findlay : Acceleration of the Carcinogenetic Action of Tar by Radiant Energy.

A. N. Goyle : The Virulence and Toxigenicity for Mice of "Normal" and "Rough" Forms of *B. enteritidis* Gaertner.

Wednesday, Feb. 18th.

HISTORY OF MEDICINE : at 5 P.M.

Paper :

Mr. G. E. Gask : The Medical Staff of Edward III.

Exhibitions :

Mr. W. Reeve Wallace and Dr. N. G. Horner : A Paduan Diploma of 1628.

Dr. Arthur T. Davies : A Diploma of Montpellier.

Thursday, Feb. 19th.

DERMATOLOGY : at 5 P.M. (Cases at 4 P.M.)

Cases :

Mr. Haldin Davis : Late Post-X Ray Pigmentation.

Dr. H. Semon : (1) Widespread Cicatrising Streptothrix Infection. (2) Lichen Planus of Mouth and Lips.

Dr. H. MacCormac : Mycosis Fungoides (15 Years' Duration).

Dr. MacCormac and Dr. Cockayne : Lupus Pernio.

Dr. Dowling : Pseudopellade following Lichen Planus (and two other cases).

Paper :

Dr. Aldo Castellani : Observations on Some Skin Diseases Common in Central America (illustrated with lantern slides, microscopical sections, &c.).

Friday, Feb. 20th.

ELECTRO-THERAPEUTICS : at 8.30 P.M.

Papers :

Dr. Norman MacDonald : The Influence of Spinal Manipulation and Adjustment on Certain Types of Cases.

Dr. R. M. Beath : Dysostosis Cleidocranialis Hereditaria.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 16th.—9 P.M., Sir Bernard Spilsbury : Wounds and Other Injuries (First Lettsomian Lecture).

HARVEIAN SOCIETY OF LONDON.

THURSDAY, Feb. 19th.—8.15 P.M., Clinical Meeting at St. Mary's Hospital.

ROYAL SOCIETY OF TROPICAL MEDICINE AND

HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, Feb. 19th.—8.15 P.M., Prof. B. Blacklock will read a paper on Schistosomiasis and Goitre in Sierra Leone (illustrated by lantern slides). Preceded at 7.45 by a demonstration on the Pathology of Experimental Leishmaniasis in the Hamster, by Dr. Henry Meloney, of Peking.

CHelsea CLINICAL SOCIETY.

TUESDAY, Feb. 17th.—8.30 P.M. (at the Club Room, St. George's Hospital, entrance in Knightsbridge), Sir Thomas Parkinson and Mr. A. Ralph Thompson will open a discussion on Some Diseases Common to the Climacteric (both sexes).

TUBERCULOSIS SOCIETY, 1, Upper Montague-street, Russell-square.

FRIDAY, Feb. 20th.—8 P.M., Dr. Clive Riviere : Lantern Talk on Pneumothorax.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Feb. 16th.—5 P.M., Mr. C. P. G. Wakeley : The Aetiology, Pathology, and Treatment of Ectopic and Imperfect Descents of the Testes.

WEDNESDAY.—5 P.M., Dr. G. S. Williamson : The Anatomy and Physiology of the Thyroid Apparatus.

FRIDAY.—5 P.M., Conclusion of Dr. G. S. Williamson's lecture.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 16th. to SATURDAY, Feb. 21st.—WEST LECTURE HALL, Royal Society of Medicine. Lecture arranged by the Fellowship of Medicine and open to all members of the medical profession. Friday, Feb. 20th, 5.30 P.M., Sir James Dundas-Grant on Some Points in the Diagnosis and Treatment of Tuberculosis and Cancer of the Larynx.—NORTH-EASTERN POST-GRADUATE COLLEGE (Prince of Wales's Hospital, Tottenham). Intensive Course in Medicine, Surgery, and the Special Departments. With the exception of Saturday, work will begin at 10.30 A.M., continue until 5.30 P.M., and will include Demonstrations, Medical and Surgical Clinics, Operations and opportunity for study in the Special Departments—COMBINED COURSE IN DISEASES OF CHILDREN, Paddington Green, Victoria Hospital, and the Children's Clinic. Two sessions daily.—LONDON LOCK HOSPITAL, 91, Dean-st., W. Comprehensive Course, clinical work daily, and lectures.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, Leicester-square, W.C. Demonstrations daily in the various departments. Pathological demonstrations arranged for, and Tuesday and Thursday special lectures. Tickets for this particular course from the Fellowship.—LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, N.W. Tuesday and Thursday, 2 P.M. Clinical demonstration by Dr. G. C. Low and Dr. Manson-Bahr.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 16th.—4.30 P.M., Mr. J. Sherren, C.B.E. :

Appendicitis.

TUESDAY.—4.30 P.M., Dr. F. G. Crookshank : Home Treatment of Diabetes.

WEDNESDAY.—4.30 P.M., Mr. H. W. Carson : Cancer of the Colon.

THURSDAY.—4.30 P.M., Dr. C. F. Hadfield : Spinal Anæsthesia.

FRIDAY.—4.30 P.M., Mr. J. Howell Evans : Cysts and Cystic Conditions of the Neck (lantern).

SATURDAY.—11 A.M., Dr. Frederic Thomson (at the North-Eastern Fever Hospital) : The Early Diagnosis of the Infectious Fevers.

Daily.—Intensive Course : 10.30 A.M. to 12.45 P.M., Demonstrations of Clinical Methods ; 2 to 3 P.M., Demonstration of Groups of Selected Cases ; 3 to 4 P.M., Clinics in General and Special Departments ; 4.30 P.M. Clinical Lectures.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE : FEB.—MARCH, 1925.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Feb. 16th.—2 P.M. Out-patient Clinic : Dr. Hinds Howell. 3.30 P.M., Subacute Combined Degeneration : Dr. Riddoch.

TUESDAY, Feb. 17th.—2 P.M., Out-patient Clinic : Dr. Adie. 3.30 P.M., Symptomatology of Cerebral Tumours : Dr. Grainger Stewart.

THURSDAY, Feb. 19th.—2 P.M., Out-patient Clinic : Dr. Kinnier Wilson. 3.30 P.M., Methods of Testing the VIIIth Nerve (in O.P. Department) : Mr. Just.

FRIDAY, Feb. 20th.—2 P.M., Out-patient Clinic : Dr. Gordon Holmes. 3.30 P.M., Recovery from Streptococcal Meningitis Complicating Otitis Media : Mr. Sydney Scott.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.

THURSDAY, Feb. 19th.—12 noon, The Cerebro-spinal Fluid, Physiology and Pathology : Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

MONDAY, Feb. 16th.—12 noon, Afferent Paths and Physiology of Sensation : Dr. Hinds Howell.

The Fee for this Course will be £2 2s.

Dr. H. J. Macbride will give a COURSE OF EIGHT CLINICAL DEMONSTRATIONS chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM, in the Wards at 10 A.M. on Tuesdays and Fridays, if sufficient entries are received. The Fee for this Course will be £2 2s.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.

WEDNESDAY, Feb. 18th.—3.30 P.M., The Optic Nerve : Mr. Leslie Paton.

Applications for this Course should be made early. Fee £5 5s. if taken as a separate Course, or £3 3s. if taken with the General Course.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M. or at such other times as may be announced.

Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole course.

Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.

J. G. GREENFIELD, Dean of Medical School.

ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE, West Smithfield, E.C.

MONDAY Feb. 16th.—5 P.M. (and on Tuesday, Wednesday, and Thursday at the same hour). Sir William I. de C. Wheeler : Some Practical Considerations and Experiences in the Conservative Treatment of Fractures of the Pelvis and the Lower Extremity.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith.

MONDAY, Feb. 16th.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Dept.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrill: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—11 A.M., Sir Henry Simson: Gynaecological Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL POST-GRADUATE LECTURES, Marylebone-road, N.W.

THURSDAY, Feb. 19th.—5 P.M., Mr. T. B. Davies: Clinical Aspects of Abortion.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 19th.—4 P.M., Mr. Higgins: Intussusception.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Feb. 17th.—5 P.M., Dr. Wilfrid Fox: Cutaneous Syphilis.

THURSDAY.—5 P.M., Dr. Wilfrid Fox's lecture concluded.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES, (At 3.30 P.M.)

MONDAY, Feb. 16th.—(At the Samaritan Hospital.) Dr. Burns: Significance of Uterine Hæmorrhage in Gynaecological Diagnosis.

TUESDAY.—(At the Maternity Hospital.) Dr. Leith Murray: Cæsaréan Section.

THURSDAY.—(At St. George's Skin Hospital.) Dr. Barendt: Skin Cases.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE (at Whitworth-street West Branch).

FRIDAY, Feb. 20th.—4.30 P.M., Dr. F. H. Lacey: Antenatal Management.

ANCOATS HOSPITAL, MANCHESTER.

THURSDAY, Feb. 19th.—4.30 P.M., Mr. Diggle: Diseases of the Oesophagus.

ROYAL INSTITUTION OF GREAT BRITAIN, 21, Albemarle-street, W.

FRIDAY, Feb. 20th.—9 P.M., Prof. T. H. Pear: Acquiring Muscular Skill.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

TUESDAY, Feb. 17th.—4 P.M., Dr. Elliot and Dr. Skene: Albuminuria in Diseases other than those Primarily of the Kidney. Discussion.

THE PEOPLE'S LEAGUE OF HEALTH.

Lectures on What We Should Eat and Why, at the Medical Society of London, 11, Chandos-street, W.

WEDNESDAY, Feb. 18th.—6 P.M., Prof. R. H. A. Plimmer: Diseases Caused by Badly Chosen Diets.

Appointments.

Willesden General Hospital, Harlesden-road, N.W.: FAULKNER, H. A., M.R.C.S., L.R.C.P. Lond., has been appointed Honorary Anaesthetist: HARVEY, F. MELVILLE, M.R.C.S., L.R.C.P. Lond., a Member of the Honorary Medical Staff.

Certifying Surgeons under the Factory and Workshop Acts: ARNOTT, T. F., M.B., Ch.B. Glasg. (Bovey Tracy); KIRKMAN, A. H. B., F.R.C.S. Edin., L.R.C.P. Lond., M.R.C.S. (Staplehurst).

Vacancies.

For further information refer to the advertisement columns.

Birmingham and Midland Eye Hospital.—H.S. £110.

Birmingham City Sanatorium.—Asst. Tub. O. and Asst. M.O. £450.

Blackpool, Victoria Hospital.—Asst. H.S. £120.

Brighton, New Sussex Hospital.—H.S. £50.

Bristol, Cossham Memorial Hospital, Kingswood.—Res. M.O. £150.

Bristol General Hospital.—House Appts. All at rate of £80.

Bristol Royal Infirmary.—Obstet. and Cas. H.S.'s. Each £100. H.P.'s and H.S.'s. Each £80. Also Dent. H.S. £116.

Bury and District Joint Hospital Board.—Res. Asst. Med. Supt. £400.

Cardiff City Mental Hospital, Whitchurch, near Cardiff.—Res. Clin. Asst. 50 guineas for six months.

Chelsea Hospital for Women, Arthur-street, S.W.—Reg. £50.

Darlington Education Committee.—Asst. Sch. M.O. £600.

Dorset Mental Hospital, Herrison, near Dorchester.—Third Asst. M.O. £300.

Exeter, Royal Devon and Exeter Hospital.—Sen. H.S. £250.

Hampstead, New End Hospital.—Sen. and Jun. Res. Asst. M.O.'s, at rate of £250 and £150 respectively.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Med. Reg. £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Surg. Reg. £300.

Ipswich, East Suffolk and Ipswich Hospital.—Election of Visiting Staff.

Kettering and District General Hospital, Northampton.—R.M.O. Leeds University, Dept. of Pathology and Bacteriology.—Lecturer in Bacteriology. £500.

Lincoln City and County Borough.—M.O.H. £900.

Madras and Southern Mahratta Railway Co., Ltd.—Dist. M.O. Rs.1550 per mensem.

Manchester City.—Asst. Tub. O. £620 19s. 9d.

Manchester, Monsall Hospital for Infectious Diseases.—First Asst. M.O. £600. Also Jun. Med. Asst. £350.

Manchester, Royal Manchester Children's Hospital.—Asst. M.O. at rate of £150.

Manchester, St. Mary's Hospitals.—Res. Obstet. O. and Res. Surg. O. Each £200.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Hon. P. in charge of Electrical and Massage Depts.

Nottingham General Hospital.—Pathologist. £350 and private fees allowed.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—H.S. at rate of £100.

Royal Chest Hospital, City-road, E.C.—Phys. Also M.O. in charge of Tuberculosis Dispensary. £750.

Royal Northern Hospital, Holloway, N.—Res. M.O. £200. Also Asst. Surg. O. £150.

St. Marylebone Hospital, W.—Visiting Consulting Dental S. £50.

St. Pancras Dispensary, 39, Oakley-square, N.W.—Hon. P. and Hon. Ophth. S.

St. Thomas's Hospital.—Res. Asst. Surg.

Western Ophthalmic Hospital, Marylebone, N.W.—Sen. and Jun. H.S.'s at rate of £150 and £100 respectively. Also Hon. Dental S.

West Ham County Borough.—Asst. Sch. M.O.'s. £600.

West London Hospital, Hammersmith-road, W.—Hon. Surg. Reg. £100.

Windsor, King Edward VII. Hospital.—Secy.

Wolverhampton and Staffordshire Hospital.—H.S. at rate of £150.

York City Council.—M.O.H. and Sch. M.O. £1000.

The Chief Inspector of Factories, Home Office, London, S.W. announces the following vacant appointments: Buntingford, Herts; Tenterden, Kent; Misterton, Notts.

Births, Marriages, and Deaths.

BIRTHS.

DOUGLAS.—On Feb. 4th, at a nursing home, Reading, the wife of Dr. A. McDonald Douglas, The Grange, Silchester, of a son.

JOLL.—On Feb. 6th, at a nursing home, the wife of Cecil A. Joll, M.S. Lond., F.R.C.S. Eng., of Harley-street, of a son.

LISCOMBE.—On Dec. 29th, 1924, at Syriam, Burma, the wife of R. H. Liscombe, M.B., B.S., of a son.

PLATTS.—On Feb. 3rd, the wife of Dr. S. Goodman Platts, Clifton Lawn, York, of a son.

SKENE.—On Jan. 31st, at Sotby Rectory, Lincolnshire, the wife of the Rev. C. M. B. Skene (Dr. Charlotte Grace Skene, M.B., B.S.), of a son.

MARRIAGES.

DODD—LODGE.—On Feb. 3rd, at the Chapel of the Charterhouse, Dr. Fredck. H. Dodd, of Devonshire-place, W., to Kathleen Elizabeth, youngest daughter of Alfred Lodge, Esq., of Banbury-road, Oxford.

LAWRENCE—ZIMMERMAN.—On Feb. 5th, by licence, at Poplar, London, George S. Lawrence, M.B., to Deenah L. Zimmerman, only daughter of Mr. and Mrs. Zimmerman, Nottingham.

M'QUADE—BURKE.—On Jan. 28th, at the Parish Church, Chertsey, Surrey, Cecil Emrys M'Quade, M.B. Dub., F.R.C.S.E., of Harcourts, Chertsey, to Rosalind, youngest daughter of Mr. and Mrs. Edmund Burke, Cowley House, Chertsey.

RICHARDSON—BIRKHEAD.—On Feb. 3rd, at St. John's, Boscombe, very quietly, Walter Silverwood Richardson, M.D., F.R.C.S. Edin., of Melbury, Boscombe, Bournemouth, to Maud Alice Birkhead, of Aston Grays, Bournemouth.

DEATHS.

BROWN.—On Feb. 2nd, at Glentworth-street, Limerick, Brig.-Surgeon Lieut.-Colonel Henry Thomas Brown, M.D., late Army Medical Staff, aged 81 years.

CHEESMAN.—On Feb. 6th, at Church Lane House, Lymington, Hants, George Edward Alexander Cheesman, L.R.C.P., L.S.A., &c., aged 71.

COLLINS.—On Feb. 3rd, at St. Andrew's, Lyme Regis, Brigade-Surgeon Francis Collins, M.D., late 5th Northumberland Fusiliers, in his 93rd year.

CRICHTON.—On Feb. 6th, at Brompton, Egbert Aubrey Lennox Chichlow, M.R.C.S., L.R.C.P., of Trinidad, aged 30.

CRITCHETT.—On Feb. 9th, at a nursing home, following an operation, Sir Anderson Critchett, Bart., K.C.V.O., F.R.C.S., Surgeon-Oculist to the King, of Harley-street, W.

ROWS.—On Jan. 28th, at 65, Rectory-lane, Prestwich, Richard Gundry Rows, C.B.E., D.Sc., M.D., Pathologist to the County Mental Hospital, Prestwich, younger son of R. G. Rows, The Willows, Helston.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

COLONIAL HEALTH REPORTS.

TURKS AND CAICOS ISLANDS.

THE population of these islands at Dec. 31st, 1923, was estimated at 5697. During the months of March and April the Turks Islands were visited by a rather severe epidemic of dysentery. Some of the cases had all the symptoms of cholera. At that time cholera was epidemic both in Haiti and Santo Domingo, and no doubt it was imported here through intercourse with those places. There were ten cases of the pulmonary type of tuberculosis during the year—about the average number. Malaria is always present to some extent. There were three cases of syphilis under treatment. Pellagra has been prevalent during the last few years. Although the islands are within the tropics the climate is not unhealthy. The severe heat in the hot months is tempered by the constant sea breezes. The temperature ranges from 60° F. minimum to 93° F. maximum, and the rainfall in 1923 was 25.10 inches. The islands are administered as a dependency of Jamaica.

Fiji.

According to the census of 1921 the population was 157,266, comprising 84,475 native Fijians, 60,634 Indians, 3878 Europeans, and some Polynesians and others. The general health of the natives during 1923 was satisfactory. The birth-rate for the period was 32.24 per 1000 and the death-rate 22.53 per 1000. Apart from a widespread epidemic of a mild type of influenza, from which only a few deaths resulted, no serious epidemic of infectious diseases occurred. A few small groups of cases of typhoid were reported, but in no case did the disease become epidemic. The decrease in the number of dysentery cases was maintained, and this once prevalent disease is now of comparatively rare occurrence. Over 4000 injections of salvarsan or neokharsivan were administered, and have effected a considerable reduction in the number of cases of tertiary yaws and kindred diseases. The campaign conducted under the auspices of the Rockefeller Foundation for the eradication of ankylostomiasis or hookworm was continued with vigour; 40,000 individuals, of which number one-half were Fijians, received treatment. There is no doubt that the wholesale treatment of the natives for this prevalent disease effects an improvement in the physical conditions of the race. The native medical practitioners, who exercise constant supervision over the health of the natives in the country districts, treated 25,000 cases of major and minor ailments during the year. Fiji is exceptionally healthy for a tropical country. It is protected against most of the infectious fevers by its distance from a continent. The absence of the anopheles mosquito prevents the occurrence of malaria. Plague, yellow fever, small-pox, or cholera have never gained admittance. Neither scarlet fever nor diphtheria appears to flourish, and first attacks of appendicitis hardly ever occur. Intravenous injection continues to give good results in leprosy, and several more cases have qualified for discharge from the asylum. Education through native medical practitioners and other means is removing from the native mind the belief in the desirability of infection of children with yaws. The salvarsan group of drugs is much sought after and, if funds allow, it is now practicable to consider the eradication of a disease almost as deadly in its after-effects as syphilis is elsewhere. The climate is generally unsatisfactory for those suffering from tuberculosis or asthma. The moist heat has an enervating effect on the nervous system. The total rainfall recorded at Suva during the year was 109.38 inches. The mean shade temperatures at Suva for the year were 70.4° F. minimum and 81.0° F. maximum.

GIBRALTAR.

The Hon. C. W. J. Orr, C.M.G., Colonial Secretary, in his report for 1923 states that the estimated total civil population of the colony at the close of the year was 17,346, of whom 16,042 are fixed residents. These figures represent the population between sunset and sunrise; to calculate the daily population it is necessary to add some 8000 aliens and 1500 British subjects resident in the neighbouring Spanish town of La Linea, who come into Gibraltar daily. The number of births during the year was 365, of which 176 were boys and 189 girls. The birth-rate per 1000 was 22.57. The births refer to the fixed population only, as, under the Aliens Order in Council, no alien may give birth in the colony; 294 deaths were registered—148 males and 146 females—and the crude death-rate was 16.95 per 1000. Infantile mortality was 109.5 per 1000 and deaths from pulmonary tuberculosis 1.2 per 1000. The number of deaths from cancer was 18, an increase of three on the number

for the previous year. The general health and sanitary conditions of Gibraltar throughout the year were excellent, and, with the exception of an outbreak of scarlet fever of a mild nature, there was no disease in epidemic form. The sanitary work of the colony is carried out by the City Council, who have also charge of roads, lighting and hygienic measures in dwellings, and the provision of water-supply.

BRITISH GUIANA.

Mr. O. Webber, Acting Assistant Colonial Secretary, in a report on the affairs of the Colony for the year 1923, states that the estimated population on Dec. 31st was 299,199 (151,960 males and 147,239 females). The birth-rates and death-rates per 1000 of the estimated population of each of the several races representing the community were as follows:—

	Birth-rate.	Death-rate.
Europeans other than Portuguese	11.3	11.9
Portuguese	24.8	30.4
East Indians	31.2	31.5
Chinese	33.0	22.9
Aborigines	31.0	29.4
Blacks	28.8	27.2
Mixed races	37.1	19.8

Of the births registered 4279, or 47 per cent., were legitimate, and 4830, or 53 per cent., illegitimate. The number of deaths of children under 1 year of age was 1609, or 177 per 1000 births.

The climate, although warm, is distinctly cooler than that of other British colonies in tropical latitudes, and Europeans and northern races enjoy consistently good health. The mean temperature throughout the year was 80.1° F., the mean maximum being 85.2° and the mean minimum 75.1°. The rainfall was 80.63 inches. The Colony, it is interesting to note, is the only British possession on the South American continent.

TRINIDAD AND TOBAGO.

In the report for 1923, prepared by Mr. T. A. V. Best, Colonial Secretary, it is stated that the estimated population of the two islands on Dec. 31st was 378,184. The white population is chiefly composed of English, French, Spanish, and Portuguese. The large majority of the inhabitants are natives of the West Indies of African descent, the balance being made up of East Indians, estimated at 122,362, and a small number of Chinese. The birth-rate was 34.70 per 1000 and the death-rate 20.89 per 1000. The number of deaths of children under 1 year was 1695. The death-rates per 1000 from the principal diseases were diarrhoea and enteritis, 1.39; malaria, 2.06; tuberculosis, 1.30; dysentery, 0.52; enteric fever, 0.38; ankylostomiasis, 0.67.

The year was a very healthy one, the birth-rate being high and the death-rate and infantile mortality reaching a low record for the colony. Venereal clinics on modern lines continue to be well attended at the out-patients' departments of the colonial hospitals, Port of Spain and San Fernando. On the recommendation of the Central Board of Health, drainage schemes for the control of malaria are being continued in the country districts. The intensive treatment of hookworm disease was continued by the Rockefeller International Board of Health. The Central Board of Health coöperated by enforcing the establishment of latrines in advance of the treatment in the areas about to be operated in. The following hospital accommodation is provided: Colonial Hospital, Port of Spain, 340 beds; San Fernando Hospital, 123 beds; the Government District Hospitals in Tobago, and at Arima, St. Joseph, Tacarigua, Couva, Princes Town, and Cedros, 248 beds. There are also small temporary hospitals at Sangre Grande, Mayara, and Toco. The climate of Trinidad is tropical and may be divided into two seasons, a dry one from January to the middle of May, with an average rainfall of 2 to 3 inches per month, and a wet season from June to December with an average of 8 inches per month. The coolest months of the year are December to April. The average temperature during the day is 84° and during the night 74° F. The average rainfall in 1923, from records taken at 119 stations, was 70.24 inches. Hurricanes are unknown. The climate is healthy and by no means hurtful to Europeans, provided reasonable precautions are taken.

WHO WAS JACQUES?

To the Editor of THE LANCET.

SIR,—A question was asked under this heading in THE LANCET of Jan. 3rd, p. 60. I have ascertained that Messrs. Jacques, Coles, and Fanshaw were not in business for themselves, but were all employees of the existing firm of Messrs. William Warne and Co., Ltd., 29, Gresham-street, London, E.C. I am, Sir, yours faithfully,

Feb. 3rd, 1925. W. A. DE B. MACLAREN,
Editor, *The India Rubber Journal*.

MOULDS AND LAUNDERING.

THE problem of how to give woollen underwear a longer lease of life can hardly be looked upon as a line of research likely to prove immediately profitable to the manufacturer; but Mr. John A. Bolton, of the Chilprufe Mills, Leicester, whose investigations were recently commented upon in THE LANCET, takes the wider view that equally with him who makes two blades of wheat to spring where before grew only one, he who can make one woollen vest live the life of two is a benefactor to humanity. Mr. Bolton has recently summed up the result of his researches to date in a small brochure which, in spite of a somewhat flamboyant style, makes very interesting reading. The author has been able to demonstrate that even after the most careful laundering large quantities of foreign matter can be extracted from woollen garments. This foreign matter consists of a basis of calcium and magnesium soaps, together with moulds, bacteria, and odds and ends of all descriptions. It is to the moulds that the chief interest attaches; the author gives suggestive photographs showing the manner in which the wool fibres are split and destroyed by these fungi, and there can be little doubt that the phenomenon of "felting" of woollen garments and their subsequent decay is due to their activity. The calcium and magnesium soaps which harbour the moulds are formed in the process of laundering, partly from these elements excreted in the sweat and urine and partly from calcium and magnesium in solution in the water used. Being insoluble, they remain behind even after thorough rinsing. Their presence is apparently inevitable when ordinary soap is used. To find some economic substitute for soap which will not form these insoluble bodies is now the goal of Mr. Bolton's researches.

THE SPAS OF FRANCE.

WE have received a pictorial guide to the Spas of France, which has been edited by a medical committee of the Offices Français du Tourisme, whose English address is 56, Haymarket, London, S.W. 1. The guide contains an account of more than 80 French medical watering-places, together with clinical indications of the use of the water and general information of a practical character for the benefit of practitioners in advising their patients. The preface claims certain advantages for French spas and is particularly addressed to medical men, who will appreciate the classification of the various thermal stations as set out in the guide, the completeness of equipment and material organisation being used, more or less, as a gauge to the space allotted to detailed description. There is no doubt that there are health resorts, as in other countries, where at present the installation is imperfect; they may possess natural advantages, but are without complete installations or facilities for visitors. France is rich in mineral-water springs, and their variety in type provides a wide range of therapeutic applications, facts which have created in the French nation what may be called the spa habit. In addition to the more generally known stations there are numerous small ones scattered about the country which are used by the French people with great advantage to themselves, but which do not meet the needs of the foreign sojourner, unless he is prepared for the limitations. Then any of these may become the ideal place for recuperation. We recommend this compendium of agreeable health notes to our readers, believing that they may often find in it the precise sort of information they need for their patients.

HOME WORK FOR CHILDREN.

THE Medical Officers of Schools Association issued some time ago a questionnaire on home work dealing with (1) the number of hours of work; (2) time devoted to games; (3) whether home work was diminished—e.g., on medical grounds; (4) whether home work was excessive; (5) the presence of definite evidence of fatigue; and (6) holiday tasks. Replies were received from a small number of schools grouped under the following headings:—Boys' and Girls' Public Schools, Boys' and Girls' Secondary Schools, and a few Mixed Schools. The replies were analysed, but it has not been found possible to arrive at any conclusions of real value from them. Some of the hours per week appeared extraordinarily long, but fatigue was stated not to exist in some of the schools with the longer time-tables. Again, the classes of the schools were hardly comparable. There is bound to be evidence of individual fatigue both from work and games in any large school, but, so far as the evidence elicited from these replies goes, there did not appear any ground for supposing that it was present to any extent in the four classes of schools under consideration. The Council of the Medical Officers of Schools Association have decided, however, that a fuller and more detailed questionnaire would be required in order to obtain the necessary data. With this object in view they have appointed a small subcommittee to draw up and issue another questionnaire.

"YESTERDAYS."

AN unpretentious and intimately written little volume with this title, which possesses certain points of medical interest, has reached us from Messrs. Fleming, Revell and Co., of New York. The book is an autobiography of Mrs. Louise Seaman Bainbridge, the daughter of one of the first women to qualify in medicine in the United States and the mother of a well-known American surgeon. Mrs. Bainbridge records that her own mother was the wife of a large boot manufacturer in Cleveland, Ohio, and took a prominent part in establishing the first medical college in that State to which women were admitted, and at which she herself later graduated and finally became its president. Mrs. Bainbridge herself, as "Sister Ohio," was nurse in the Federal army during the American Civil War, when there were no trained nurses in the country, and has personal recollections of a meeting with President Lincoln. After the war she travelled widely with her husband and her young son, and has been able to recollect vividly and set down clearly events and scenes in many lands, notably in the Far East and China. The chief part of the work is a record of family life, but the descriptions interspersed give a general interest to a little book dealing genially with bygone days.

DONATIONS AND BEQUESTS.

As showing what a well-organised and systematic effort can do in aid of a local hospital by a committee almost entirely composed of working men and women representative of the various cotton mills in the district, £1321 was raised last year in aid of the Middleton and Districts Hospitals (Lancs), the basis of contribution being a penny per week by each worker in the local mills and workshops, who voluntarily submit to this sum being deducted from their wages. With other subscriptions the total amount collected was £1590.—The "Power of the Penny," otherwise the "Penny a Week" Workers' Fund on behalf of the Kent County Ophthalmic Hospital at Maidstone, amounted to £9000. The subscribers number nearly 50,000 and the total contributions during five years to this fund came to £39,000, or more than nine million pennies.—Legacies and donations amounting to over £4000 during the last month have been received by the Manchester Royal Infirmary, including legacies of £1000 from Mr. John J. Litton, £500 each from the late Mr. Karl Seige and the late Mrs. Elizabeth Smith, and £481 from the late Mr. William Parker; from the Radcliffe Central Committee £417, and from the Hospital Sunday Fund of Haslingden, East Lancashire and Heywood £369.—Mr. George Hill Dunscombe, of Chester-square, London, in the event of the failure of certain trusts, bequeathed £5000 to the Royal Infirmary, Edinburgh; £5000 to the Queen's Hospital for Children, Hackney-road; £2000 to the Edinburgh Longmore Hospital for Incurables; £2000 to the Edinburgh Hospital for Sick Children; and £10,000 to St. Bartholomew's Hospital.—Mr. Alfred Evans, colliery proprietor, Paulton, Somerset, among other bequests, left £5000 each to Dr. Barnardo's Homes and Muller's Orphanage, Clifton, Bristol; £2000 each to the Bristol Eye Hospital, the Bristol Royal Infirmary, the Bristol General Hospital, the Alton Cripples Home, and St. Dunstan's Institute for the Blind; £1000 each to Paulton Cottage Hospital, Chorley's Homes, Canonbury, London, and to Bath United Hospital.—Miss Edith Martha Hales, Hove, left £58,796. After the fulfilment of a number of personal bequests, she gave the residue of her property, which will ultimately exceed £40,000, to the General Lying-in Hospital, York-road, Lambeth, the Society for the Prevention of Cruelty to Animals, and the Cancer Hospital, Fulham-road.—Miss Mary Eleanor Robinson, of Holmfild, Aigburth, Liverpool, left £500 each to the Royal Southern Hospital and the Home for Female Incurables, Liverpool.—Mr. David Moseley, J.P., of Buglawton Hall, Congleton, indiarubber manufacturer, Manchester, left £1000 to the Hospital for Skin Diseases, Manchester.—Mr. Adam George Rankine, J.P., of Hoylake, left £500 to the Liverpool Maternity Hospital and Ladies' Charity, £250 each to the Sheltering Home for Destitute Children, the Hoylake Day Nursery, and the Hoylake and West Kirby Cottage Hospital.

THE
Hunterian Oration

ENTITLED

JOHN HUNTER AS A MAN.

*Delivered before the Royal College of Surgeons of
England on Feb. 14th, 1925,*

BY SIR D'ARCY POWER, K.B.E., F.R.C.S. ENG.

HUNTER AS A PIONEER.

MR. PRESIDENT, LADIES AND GENTLEMEN,—Brought up, as I have been at St. Bartholomew's Hospital, in the straitest sect of the Hunterian School, I might fairly claim some knowledge of the pioneer in surgery, the anniversary of whose birthday we are assembled to celebrate to-day. Sir William Savory, my revered master, learnt from Sir William Lawrence, and he from John Abernethy, who himself sat at the feet of John Hunter and was ever afterwards his eulogist. But much as I had heard of John Hunter a reperusal of his works has shown me how little I really knew about the originality of the man, of his limitations, or of the handicaps under which he worked. It is on these subjects that I shall speak to you to-day, and my wish to do so is the greater because the principles of surgery which he laid down have fallen somewhat into the background, being overshadowed by advances in chemistry, physics, and physiology, by the advent of bacteriology, and by the work of Lister.

I want you to think first of John Hunter as a pioneer in the philosophy of surgery, not as a skilled operator. Like all pioneers, he lived and worked alone, for none of his contemporaries could think as he thought or see what he saw. Like Vesalius and Harvey, he had to educate a new generation to foster his ideas and expound his thoughts.

Limitations.—The limitations of John Hunter are obvious. He was hampered by a defective education. He had an almost mediæval respect for words as words. He could not express himself clearly either in writing or by word of mouth when he dealt with the more difficult problems of surgery which he knew existed though he was unable to solve them for want of the ancillary sciences. He was a gross teleologist. His metaphors were often strained and sometimes wholly false. He was confessedly ignorant of the work of his surgical colleagues and foreign contemporaries, and, as I shall show presently, he suffered from frequent and severe attacks of illness which would have incapacitated anyone possessed of a less dauntless spirit. But when we have said this we have said all there is to say against him as a man.

Handicaps.—Now consider his handicaps. There was no chemistry in his day, no physics, no acquaintance with minute anatomy, for the microscope was not yet in common use, no knowledge of animal cells, hardly even a theory of fermentation to account for disease, because humoral pathology and the doctrine of climatic conditions still held sway.

Joseph Black discovered "fixed air" or carbon dioxide in 1754; Priestley prepared "dephlogisticated air" in 1774. Three years later Lavoisier called it "respirable air" or "oxygen," and taught the true nature of the interchange of gases in the lungs. Hunter by this time had done much of his work on respiration. The want of a well-calibrated thermometer vitiated many of his experiments on animal heat. He was obliged, therefore, to stumble along and explore the fields of surgical knowledge as best he could, for he was half a century before his time. He would have gotten the true explanation of many of his facts had he been born in 1778 instead of in 1728. With all these limitations and handicaps he often arrived very nearly at the truth, and his writings are full of the most astounding presages of knowledge to come,

presages which have been fulfilled for the most part by the advance of science, although some still await their accomplishment.

Animal Heat.

Hunter's methods and the advances he made are nowhere seen to better advantage than in his experiments and observations on animals in regard to their production of heat. Just a century earlier his great predecessor, William Harvey, who equalled him in originality of thought and excelled him in logical exposition, had dealt with the subject of animal heat in the seventy-first essay of his treatise "*De Generatione Animalium*." John Mayow had solved the problem at Oxford in 1674, but he died young and the "*Tractatus Quinque*" fell stillborn from the press. He left no successor; his discoveries had to be made afresh and applied by others more than a hundred years later. Albert Haller, who did so much to advance physiology in general, was not particularly interested in the subject of animal heat, so there had been no material change of thought about it in the century which separated Harvey from Hunter. It is fair, therefore, to compare the two monographs, bearing in mind that Harvey was already well-stricken in years when he wrote on "*calidum innatum*," whilst Hunter—aged 38—was in the prime of life when he performed his experiments, although they were not elaborated and published until 20 years afterwards.

Harvey is trammelled throughout by his knowledge of history; his treatise is filled with quotations from Aristotle, yet he arrives at the very practical conclusion that the heat of the blood in animals during life is neither fire nor derived from fire as the ancients thought. It is a principle inherent in the blood, but he then loses himself in speculating whether or not the blood is the Soul or Life itself.

Hunter starts in a very different manner. The lapse of 100 years had given him an instrument of precision—the mercury thermometer invented by Fahrenheit in 1720—whilst the work of Black had afforded some insight into the composition of the atmosphere and the interchange of gases. But the science of physics had not advanced sufficiently to enable Hunter to appreciate the relationship of heat to cold. He speaks of animals which "seem to possess a power of generating cold," whilst to him, as in the time of Harvey, heat was still a principle. How new an instrument the thermometer was is shown by a letter to Jenner on July 6th, 1777, in which Hunter says:—

"The thermometer is very useful when understood. You will observe the scratch upon the glass stalk, perhaps about 2 inches from the globe, which is the freezing point. Put 0 or nought which is upon the ivory scale 2 degrees below the scratch, the 0 becomes the thirtieth degree and the scratch being 2 degrees above it stands at the freezing point; then from that count upwards; or, if the cold is below 30 then put 1 or 2 at the scratch and count down; every No. is 10 degrees. What the devil becomes of your eels in the Winter? but try them in the Summer and see what you can make of them."

Jenner does not seem to have been very fortunate in his management of the thermometer. A few years later Hunter writes chaffingly to him: "You are very sly although you think I cannot see it. You very modestly ask for a thermometer. I will send you one, but take care that those damned clumsy fingers do not break it also." Nevertheless, even with such inadequate instruments Hunter set out to determine experimentally the cause of animal heat not only in different vertebrata and invertebrata, but also in the vegetable kingdom. He came to the conclusion that "animal heat is owing to some decomposition going on in the body in pretty regular progression, though it is not the process of fermentation." He thus gave for the first time the correct answer to a problem which had baffled philosophers from the earliest days. He then adds the very important statement: "I expect the blood has an ultimate standard heat in itself when in health and that nothing can increase that heat but some universal constitutional affection." Ignorance of the functions of the nervous system prevented him

from studying the mechanism of heat regulation in animals, though he distinguished clearly between the homoiothermic and the poikilothermic—the warm and the cold-blooded—for he says “the expression should rather be animals of a permanent heat in all atmospheres and animals of a heat variable with every atmosphere.” A strange perversity led him to spoil his result, for he limits the place of heat production to “some part of the body, perhaps the stomach,” and by ill fortune it did not occur to him to measure the fever in disease.

The Causes of Disease.

The shifts to which John Hunter was put to explain the general principles of disease in his ignorance of micro-organisms are both interesting and ingenious. He was in the position which we occupied until lately in regard to tubercle and syphilis and where we still stand about cancer. He knew the clinical facts but could not interpret them, for he had no knowledge of the part played by micro-organisms.

How near he got to the truth is shown by his definition of disease when he says: “The most simple idea I can form of an animal being capable of disease is that every animal is endued with a *power of action* and a *susceptibility of impression*, which *impression* forms a *disposition*, which *disposition* may produce *action*, which *action* becomes the immediate *sign* of the disease; all of which will be according to the nature of the impression and of the part impressed.” This seems at first sight to be a mere cloud of words hiding nothing. Interpret it by latter-day knowledge and it shows how far Hunter had advanced in surgical pathology. What he calls the *power of action* we now speak of as the *predisposition* to disease or the *diathesis*; the *susceptibility of impression* is the *infective organism*; the *disposition* is the *exciting cause*, and the *action* is the *manifestation of the disease by signs and symptoms*. Take tuberculous arthritis as an example. The tuberculous diathesis (*power of action*) allowed the tubercle bacillus (*the susceptibility of impression*) to settle in the joint in consequence of a sprain (*the disposition*), and the joint then became hot and swollen (*the action*).

He says, indeed: “A true specific disease is one that probably cannot arise but from one cause and which probably always belongs to morbid poisons.” He gives as an example “Scrofula, which is one of those diseases that is supposed to be hereditary, but it is only a readiness to fall into the peculiar action when properly irritated that is hereditary, and when such a cause does not exist we find no scrofula.”

Surely *nil nisi clavis deest*, the key alone is wanting, and the key was not forged until Pasteur and Lister—the master locksmiths—came to maturity more than 70 years after the death of John Hunter. He was even a little in advance of the earliest Listerian teaching, for he showed by experiment that “air simply has no power to excite inflammation.” He returns over and over again to the problem of the causation of disease when he is considering the causes of inflammation. Thus he says: “It is the *cause* producing inflammation which is the disease and not the inflammation itself, for all inflammations that can be called diseases have specific causes.” And he is driven at last to confess that “inflammation may arise from a vast variety of causes with which we are at present unacquainted, nay, which we do not even suspect.”

THE HUNTERIAN SCHOOL.

If Hunter was born half a century too soon to allow of his genius giving the best results, the span of his life coincided with the time needed to establish a school of scientific surgery in this country. No great surgeons existed in England from the death of Richard Wiseman in 1676 until William Cheselden began to make his reputation by teaching anatomy privately in 1711. The industry of Mr. G. C. Peachey has shown that Hunter was not the first to hold private classes, as a demand had already grown up for more advanced teaching than was provided by the formal lectures at the United Company of Barbers and Surgeons—lectures which had once been of the greatest service

to surgery but which in process of time had become obsolete. Cheselden, Nourse, Chovet, Sharp, and Pott had lectured to large classes before Hunter, but they dealt only with their own experience and with surgery in its clinical aspects. It was left to John Hunter to invent surgical pathology. His teaching only appealed to a few, and his lectures were sometimes attended so scantily as to give point to the story of his ordering the skeleton to be brought into his lecture-theatre that he might address the audience with the usual prelude “Gentlemen.”

How then did the school spread from such small beginnings? His few pupils became the leaders of the next generation of surgeons. Sir William Blizard of the London Hospital; Henry Cline of St. Thomas's; Astley Cooper at Guy's; John Abernethy at St. Bartholomew's; Anthony Carlisle at the Westminster; William Hey at Leeds; Philip Syngue Physic and his nephew John Syngue Dorsey in Pennsylvania received the Hunterian teaching with enthusiasm. These great surgeons transmitted their knowledge in turn to Sir Benjamin Brodie, Sir William Lawrence, Joseph Henry Green, John Collins Warren, and Valentine Mott, who in their generation became teachers at the great schools of medicine in England and in America. The teaching of John Hunter was thus disseminated amongst the rank and file of the profession, whilst the doctrines he enunciated were so novel, so ingenious, and seemingly so heterodox as to become the subject of acrimonious discussion. Attention was thus drawn to them and they quickly found their way into a text-book so widely read as Benjamin Bell's “System of Surgery,” and they thus became public knowledge both at home and abroad during the lifetime of their author.

But something more is needed to account for the rapid diffusion of Hunter's teaching. It is to be found in the spirit of devoted affection which he inspired in his pupils and in all with whom he was brought into personal contact. Those, who like myself have been pupils of Huxley, of Rolleston, and of Ray Lankester, can easily enter into their feelings of hero-worship. Adams says of him: “He was almost adored by the rising generation of medical men who seemed to quote him as the Schools, at one time, did Aristotle.”

Rough, coarse, and prone to anger as he was in later life, he had the personal magnetism inherent in every great teacher, whether of religion, philosophy, science, or even quackery—a magnetism which attracts kindred spirits, rarely amongst contemporaries, generally in a younger generation. Thus it was with John Hunter. To his pupils he was “the Dear Man” with whom they were in constant communication either by letter or by word of mouth and to whom they looked for guidance and instruction in the experimental methods he had taught them to use in scientific surgery.

THE HUNTERIAN TRADITION.

The Hunterian tradition passed down the next century in two great streams, theory and practice, uniting sometimes but for the most part flowing separately, because it was only now and again that a single mind could embrace the whole. Both streams took their source in a sound knowledge of human anatomy gained by daily dissection. The streams parted early. Blizard, Astley Cooper, Hey, Physic, Gibson, and Dorsey became great operating surgeons and advanced the teaching of Hunter along the lines of arterial surgery, the anatomy and treatment of hernia, and the pathology of fractures and dislocations. John Abernethy, on the other hand, developed the physiological side of surgery and investigated the causes of disease and its non-operative treatment, for he took but little pleasure in the manipulative part of his profession.

Sir Benjamin Brodie was great enough in the second generation to combine the science with the art of surgery—the theory with the practice. He was equally good as a morbid anatomist and as a clinical surgeon, whilst his general knowledge of science enabled

him to fill with distinction the important position of President of the Royal Society. Joseph Henry Green, the Hunterian orator in 1840, alone followed Hunter on the metaphysical side and delved so deeply into philosophy that he soon lost himself in speculation and did but little to advance the practice of surgery.

Sir James Paget in the third generation developed surgical pathology on truly Hunterian lines: whilst Sir William Savory was more interested in the teaching and dissemination of the surgical principles laid down by John Hunter, though he was a skilful operator, and dearly loved to tie an artery or extirpate a tumour so placed as to demand all his knowledge of anatomy.

You, Sir, like myself and many others of the fourth generation hold firmly to the teaching of John Hunter. We recognise with thankfulness the great work which he accomplished, but we realise it was the work of a pioneer and that the fields he pointed out are being explored by methods and by instruments of which he had no conception. The museum, Sir, has always been your especial care, but you have not neglected the equally important subject of teaching both by example and precept. You have shown, too, so enlightened an interest in the habits and customs of the beasts of the field and the fowls of the air as would have drawn you very near to the heart of John Hunter had you been privileged to sit at his feet. To you also he would most certainly have been the "dear man."

THE MENTALITY OF JOHN HUNTER.

The attitude of John Hunter to Nature and the human body always had something of the poetic in it, and was akin to the feeling expressed by Longfellow when he wrote of Agassiz:

"And Nature, the dear old Nurse,
Took the child upon her knee
Saying, "Here is a story book
Thy Father has written for thee."

Hunter looked upon Nature as a conscious personality. He says: "Everything in Nature involves two consequences, the one beneficial, the other hurtful. But if we understood thoroughly all the remote causes we should probably see its utility in every case." He speaks of muscles as "being conscious of their actions and almost endowed with reason." "Nature," he says, "acts purposively in the repair of dead bone," and "the clot adheres to the side of an aneurysm from a consciousness on the part of the artery of the weakness of its wall." He says in like manner that "Nature lays claim to and removes what she pleases," and he speaks of two surfaces lying in contact with each other and "agreeing mutually not to inflame." He also maintains that the first and immediate cause of the absorption of tissues is "a consciousness in the parts to be absorbed of their unfitness or impossibility of remaining under such circumstances, the action excited by the irritation being incompatible with the natural actions in existence in the parts whatever these are: wherefore they become ready for removal or accept of it with ease."

The blood, too, is for him so living a tissue that the clot "has the power of becoming vascularised in itself," and when blisters and setons have been used as derivatives to draw off the humours he "is unable to ascertain fully how they act, that is, how far the real disease is invited and accepts the invitation."

A MARTYR TO SCIENCE.

I wish now to draw your attention to a new aspect of John Hunter's life. It has always been assumed that the statement was the truth, the whole truth, and nothing but the truth, which was made by Sir Everard Home in 1794—the year after his brother-in-law's death—that "the symptoms of Mr. Hunter's complaint for the last 20 years of his life may be considered as those of angina pectoris and form one of the most complete histories of that disease upon record."

Reading the account of his illness in the light of modern knowledge it seems to me that John Hunter

died of syphilitic disease of his arterial system, and that, in addition to the angina pectoris due to this cause, he suffered for many years from cerebral syphilis. Both conditions were due to the action of the spirochaetes with which he deliberately inoculated himself in May, 1767. He may be looked upon, therefore, as one of the great martyrs to science. Personally, I do not think he was justified in this martyrdom, for the consequences of his experiment were visited upon his children as well as upon himself, whilst all surgery suffered by the shortening of that life which was advancing its bounds in every direction.

On a Friday in May, 1767, Hunter inoculated himself with pus from a patient suffering from gonorrhoea to determine whether the poison of gonorrhoea was identical with that producing syphilis. Surely that Friday must have been May 22nd, a well-recognised "Egyptian day," or *Dies Maledicti*, when it was most unfortunate to embark upon any new undertaking. The prepuce and glans were scarified and it was noticed that the incisions itched on the second day—May 24th. The prepuce was inflamed on May 26th, and on June 2nd a small ulcer appeared and was cauterised. A slough separated on June 6th and the sore was cauterised a second time. The glans itched on June 7th, and on the following day a second slough detached itself from the prepuce whilst the sore on the glans ulcerated and was cauterised. Sloughs separated from the glans and prepuce on June 12th, and the ulcers healed leaving scars. The lymphatic glands in the right groin enlarged during the week ending June 13th, but they did not suppurate.

The rapidity with which the two seats of inoculation ulcerated and the appearance of a bubo suggest that the pus contained Ducey's bacillus causing two soft sores. Spirochaetes were also present because the gland in the groin began to enlarge again after a time, and in July the right tonsil ulcerated. Copper-coloured spots appeared on the skin in September and the tonsil ulcerated a second time. The administration of mercury soon healed the ulcer but it returned a third and a fourth time. The rash on the skin appeared on three separate occasions, and mercury was then "taken in a sufficient quantity and for a proper time." Hunter says, "to complete the cure. The time the experiments took up, from the first insertion to the complete cure, was about three years." How complete the cure was will be shown! It is certain, therefore, that Hunter also inoculated himself with the *Spirochaeta pallida* and that his mercurial course was insufficient. The gonococcus having been inoculated upon skin surfaces did not multiply.

He married Miss Anne Home on July 22nd, 1771. There is nothing to show that she became infected, as it was then understood. John Banks Hunter was born in June, 1772, and lived until 1838: Mary Anne, born in December, 1773, only lived two months. James, born in November, 1774, died in February, 1775. Agnes, the youngest child, born in 1776, lived until 1838. It may be remarked that neither of the two surviving children left offspring and neither was above the average in mental attainments.

Except for an attack of pneumonia in 1759 and occasional poisoned wounds, from which every anatomist suffers from time to time, Hunter considered himself a healthy man until the spring of 1769, when he had some toxic disturbance which, in accordance with the fashion of the time, was diagnosed as "a fit of the gout." It returned in the three following springs but not the fourth. Its place was taken in the spring of this year (1773) by his first attack of serious illness. The record reads: "In the spring of 1773, having met with something which very forcibly affected his mind, he was attacked at 10 o'clock in the forenoon with a pain in the stomach about the pylorus. The sensation was limited to those parts and became so violent that he tried change of position to procure ease. He sat down, then walked, laid himself down on the carpet, then upon chairs, but could find no relief. He took a spoonful of tincture of rhubarb with 30 drops of laudanum without the smallest benefit.

While he was walking about the room he cast his eyes on the looking-glass and observed his countenance to be pale and his lips white, giving the appearance of a dead man. This alarmed him and led him to feel for his pulse, but he found none in either arm. The pain still continued and he found himself at times not breathing. Being afraid of death soon taking place if he did not breathe, he produced the voluntary act of breathing by working his lungs by the power of the will. In this state he continued for three-quarters of an hour, during which time frequent attempts were made to feel the pulse but in vain; however, at last the pain lessened and the pulse returned, although at first but faintly, and involuntary breathing began to take place. In two hours he was perfectly recovered."

This attack of epigastric angina occurred six years after the inoculation with syphilis. It may have been caused by toxic changes in the smaller blood-vessels supplying the vagal nuclei, or it may have been the first indication of syphilitic inflammation at the root of the aorta. I am inclined to think that it was due to cerebral changes rather than to inflammation in the large arteries, for it would hardly have passed off so rapidly without leaving any marked ill-effects. It is noteworthy, too, that from this time until his death, 20 years later, Hunter drank little, if any, wine. Not, we may be sure, because he liked abstinence, but because, as he says, it went to his head.

Four years later—in 1777—and again in the spring, he was seized with a severe and dangerous illness again in consequence of anxiety of mind, as he had been obliged to pay a large sum of money for a friend for whom he had gone security and which circumstances made extremely inconvenient.

"At 2 o'clock in the forenoon he ate some cold chicken and ham and drank a little weak punch; immediately after this he went eight miles in a post-chaise. While he was on the journey he had the feeling of having drunk too much but passed the remainder of the day tolerably well; at 12 o'clock at night his stomach was a little disordered, for which he took some caraways and went to bed. He had no sooner lain down than he felt as if suspended in the air and soon after the room appeared to go round; the quickness of this motion seemed to increase, and at last it was very rapid. It continued for some time, then became slower and slower until the whole was at rest. This was succeeded by vomiting which was encouraged and gave him a good night's rest.

Next day he was tolerably well but fatigued. The morning after, thinking himself quite recovered, he went out before breakfast, drank some tea and ate some bread-and-butter which he was not accustomed to do. At 11 o'clock he felt his stomach in much the same state as before; in about half an hour the sensation of the room appearing to turn recommenced and continued for some time but not with such violence as in the last attack. He became sick and vomited. The sensation of himself and everything else going round went off, but that of being suspended in the air continued with giddiness. He could now hardly move his head from the horizontal position, and about 2 o'clock was brought home in his carriage, the motion of which was very disagreeable, giving him the sensation of going down or sinking.

"After he went to bed the giddiness and the idea of being

suspended in the air increased, and the least motion of the head upon the pillow appeared to be so great that he hardly durst attempt it: if he but moved his head half round it appeared to be moving to some distance with great velocity; the idea he had of his own size was that of being only 2 feet long, and when he drew up his foot or pushed it down it appeared to him to be moving a vast way. His sensations became extremely acute. He could not bear the least light, so that although the window blinds were drawn a curtain and a blanket were obliged to be hung up against it, the fire to have a screen before it, and the bed curtains to be drawn. He kept his eyes closed, yet if a lighted candle came across the room he could not bear it. His hearing also was painfully acute, but not so much increased as his sight. The smell and taste were also acute, everything he put into his mouth being much higher flavoured than common by which means he relished what he ate.

"He remained in this state for about

ten days; by this time he was rather better, that is, he could move his head more freely. All his ideas of his present state became natural at the end of ten days, the strange deception concerning his own size was in part corrected, and the idea of suspension in the air became less. But for some time after the fire appeared of a deep purple red. When he got so well as to be able to stand without being giddy he was unable to walk without support, for his own feelings did not give him information respecting his centre of gravity, so that he was unable to balance his body and prevent himself from falling. He gradually recovered from this state, and as soon as he was able went to Bath at the end of August, stayed there until the middle of November, and drank the waters which were thought to be of service to him. He returned to town much better and in a few weeks got quite well."

Here, again, the symptoms point to cerebral rather than to cardiac disturbance, to syphilitic inflammation of the smaller cerebral arteries, perhaps in the nature

[Copyright, Wellcome Historical Medical Museum.]

FIG. 1.—John Hunter at his house in Leicester-square just after his return from Belle Isle. The sign above the door is the golden calf, and probably the artist intended the two asses to be symbolical of the patients who were going to consult him.

of a syphilitic periarteritis. There was vertigo but neither tinnitus nor deafness, so that the auditory symptoms were due to stimulation of the vestibular nerve rather than to changes in the labyrinth. The photophobia was of retinal origin and was due to hyperæsthesia, such as led to exaltation in the senses of smell and taste. The lesions were multiple, and although the results lasted for some time, as in the case of the purple red fire, yet they were compensated in the end.

Hunter's brain adapted itself fairly well to the altered conditions for the next eight years, although his arterial system was undergoing progressive degeneration, and his friends noticed with concern that he was ageing rapidly. At the beginning of April, 1785—

"He was attacked with a spasmodic complaint which at first sight appeared slight but afterwards became very violent and terminated in a fit of the gout in the ball of the great toe. Like the previous attacks it was brought on by anxiety of mind. The first symptom was a sensation of the muscles of the nose being in motion, but whether they really were or not he was never able to determine. This sensation returned at intervals for about a fortnight, attended with unpleasant feelings in the left side of the face, lower jaw, and throat, which seemed to extend into the head on that side and down the left arm as low as the ball of the thumb, where it terminated all at once. These sensations were not constant but returned at irregular intervals. They soon became more violent, attacking the head, face, and both sides of the lower jaw, giving the idea that the face was swelled, particularly the cheeks, and sometimes they slightly affected the right arm. After they had continued a fortnight they extended to the sternum, producing the same disagreeable sensations there and giving the feeling of the sternum being drawn backwards towards the spine as well as that of oppression of breathing, although the act of breathing was attended with no real difficulty. The heart seemed to miss a stroke at these times, and when feeling the pulse the artery was very much contracted, often hardly to be felt, and every now and then the pulse was entirely stopped. He was afterwards attacked with pain in the back about that part where the œsophagus passes through the diaphragm, the sensation being that of something scalding hot passing down the œsophagus. He was next seized with pain in the heart itself, and last of all with a sensation in the left side nearly in the seat of the great end of the stomach attended with considerable eructations of wind. All these symptoms, those in the stomach and nose only excepted, were in addition to the first, for every attack began with the first symptom. The complaint appeared to be in the vascular system, for the larger arteries were sensibly contracted and sore to the touch, as far as they could be touched, principally in the left arm.

"These symptoms increased in violence at every return, and the attack, which was most violent, came on one morning

about the end of April and lasted about two hours. It began as the others had done, but having continued about an hour the pain became excruciating at the apex of the heart. The throat was so sore as not to allow the attempt to swallow anything, and the left arm could not bear to be touched, the least pressure upon it giving pain. The sensation at the apex of the heart was that of burning or scorching, which by its violence quite exhausted him, and he sank into a swoon or doze which lasted about ten minutes, after which he started up without the least recollection of what had passed or of his preceding illness. He then fell asleep for half an hour and awoke with a confusion in his head which went off in a few days."

These attacks were of a more complicated nature than the previous ones. They were due in the main to syphilitic changes taking place in the heart and

aorta, and were thus anginal in character, but in part they may have been due to alterations in the cerebral circulation. He went to Tunbridge in the August of this year, 1785, but finding no improvement there he travelled to Bath in September, and in December he was again in London, where he performed his first operation for the cure of aneurysm by ligaturing the artery in its continuity.

The attacks of angina continued, though they did not increase in severity throughout the year 1786, until he became so accustomed to them that they formed a part of his daily life. He was unable, in consequence, to take much exercise and passed his time in superintending the printing and publication of the "Observations on the Animal Economy" and the "Treatise on the Venereal Disease," which were issued from his own press in Castle-street, Leicester-square. In

the following year, 1787, Sir Joshua Reynolds painted the striking portrait which has made his appearance so familiar to all of us.

He wrote to Jenner in May, 1788, saying that a severe indisposition for three weeks had prevented him from writing, although "when two guineas tempt me I cannot resist." It is noteworthy that the first attack of these complaints was produced by an affection of the mind and every future attack of any consequence arose from the same cause, and although bodily exercise or distension of the stomach brought on slighter attacks it still required the mind to be affected to render them severe, and as his mind was irritated by trifles these produced the most violent effects on the disease. His coachman being late or a servant not attending to his orders brought on the spasms, while a real misfortune produced no effect.

About the beginning of December, 1789, he was attacked with a total loss of memory when he was spending the evening with a friend.

"He did not know in what part of the town he was, nor even the name of the street when told it, nor where his own house was. He had no conception of any place existing beyond the room he was in and yet was perfectly conscious of his loss of memory. He was sensible of impressions of all kinds from the senses and therefore looked out of the window, although rather dark, to see if he could recognise the situation of the house.

"This loss of memory gradually went off and in less than half an hour he was recovered. About a fortnight afterwards, as he was visiting his patients in the forenoon, he noticed occasionally a little giddiness in his head and by 3 o'clock it was attended by an inclination to vomit. The giddiness became severe, but went off again about 7 or 8 o'clock; about 9 or 10 o'clock it returned with more severity and when going to bed about 11 o'clock he had entirely lost his centre of gravity, although he could move his limbs as the will directed. Light became offensive and everything had a kind of yellow cast: sounds became more acute than usual; objects had lost their true direction: a perpendicular, for instance, seemed to him to lean to the left, making as near as he could conjecture an angle with the horizon of 50 or 60 degrees. Objects were also smaller than the natural recollection of them: his idea of his own size was that of being only 4 feet high: objects also appeared to be at an unusual distance as if seen through a concave glass. Motion of his head was extremely disagreeable; he therefore moved

1777, more than 12 years before, and perhaps not far away from the areas originally involved, although there is no doubt that the disease in the large arteries had made considerable progress. I am not a neurologist, but so far as a surgeon can guess the lesions may have been situated in the immediate neighbourhood of the basal ganglia or even still nearer the cerebral cortex. I do not think they were in the cortex itself, nor do the spinal cord or the peripheral nerves seem to have been affected. The subjective sensation in the nose and the pain in the great toe might help to localise them more accurately.

The illusions as to size and shape may, perhaps, be accounted for by changes occurring in those "silent areas" of the brain which it is so difficult to explore experimentally. It is certain that a generation which knew nothing of the individual functions of the brain, and which attributed every form of toxic absorption to "gout," explained the pain in John Hunter's toe as being caused by that disease, just as in later years we have been contented to say that he suffered from angina pectoris without looking farther for the cause. The permanency of the defect in vision and the impairment of memory also point to widely spread

changes in the brain which were almost certainly vascular for, as will be seen presently, no gross lesion was found after death. The sleeplessness and the increasing irritability must be attributed rather to changes taking place in his larger arteries than to lesions in the brain.

He never went to bed at this time without having an attack which was brought on by the act of undressing. They came on in the middle of the night, and the least exertion and conversation after dinner was attended by them. He felt obliged, therefore, to confine himself within a certain sphere of action and to avoid dining in large companies. Even operations in surgery, if attended with any nicety, now produced the same effects.

In the autumn of 1790 and in the spring and autumn of 1791 he had more severe attacks than

during the earlier periods of the year, but of not more than a few hours' duration. In the beginning of October, 1792, one was so violent that Everard Home, who was present, thought he would have died in it.

"The end came on Oct. 16th, 1793, when in his usual state of health, he went to St. George's Hospital, and meeting with some things which irritated his mind and not being perfectly master of the circumstances he withheld his sentiments, in which state of restraint he went into the next room and turning round to Dr. Robinson, one of the physicians of the hospital, he gave a deep groan and dropped down dead."

The post-mortem examination showed a small heart in a thickened pericardium. The coronary arteries

it with great caution, although coughing and sneezing did not affect it. The disposition to sleep was a good deal gone, an hour or two in the 24 being as much as could be obtained. These symptoms were much the same for a week and began to diminish gradually, so that in a fortnight he was able to sit up and in three weeks went for an airing in his carriage. He felt a pain in the joint of his great toe which inflamed gently but soon left it.

"His recovery from this indisposition was less perfect than from any of the others. He never entirely lost the oblique vision, his memory was in some respects evidently impaired, and the spasms became more constant."

These attacks were probably due to cerebral changes similar to those which caused the first symptoms in

were bony tubes which were with difficulty divided by the knife, when their transverse sections did not collapse but remained open. The mitral valves were partially and irregularly calcified and the aortic valves had lost their natural pliancy. The aorta, a little beyond the semilunar valves, had its cavity larger than usual, putting on the appearance of an incipient aneurysm. The inner coat of the vessel had entirely lost its natural polish and was studded with opaque white spots raised higher than the general surface. The cranium and dura mater were in a natural state but the pia mater was congested. The internal structure of the brain was carefully examined, and the different parts both of the cerebrum and of the cerebellum were found in the most natural and healthy state. The internal carotid arteries were ossified and the vertebral arteries lying along the medulla oblongata had also become bony, whilst the basilar artery had opaque white spots very generally along its coats.

THE CAUSE OF HUNTER'S DEATH.

A review of these facts about the illness and death of John Hunter show that he died with widespread disease of his arterial system—the largest as well as the smallest arteries being involved. He may have inherited some family weakness of the vascular system, for his brother William had died ten years before at exactly the same age of 65 after suffering the vague symptoms associated with arterial degeneration. The post-mortem examination of John Hunter's brain showed no gross lesions—such as a gumma—which were not likely to be overlooked by the trained anatomists who carried it out. The cerebral symptoms from which he began to suffer two years after he had inoculated himself with syphilis, and which continued intermittently until the time of his death 20 years later, were, therefore, due to lesions of a microscopic character. They were caused by cerebral syphilis of the interstitial variety, that is to say, they were due to the action of toxins produced by the *Spirochaeta pallida* in the lymphatic sheaths of the smaller blood-vessels. These changes in the outer coat of the arterioles interfered with their vasa vasorum and so with the nutrition of the middle coat, thus leading to thrombosis or even complete obliteration of the little vessels as a consequence of the endarteritis. Such a sequence of events recurred several times and were more frequent and severe as he grew older and the arteriosclerosis became more pronounced. We can only be thankful that the stress of the disease fell upon the deeper parts of the brain, and that his intellectual faculties were so little impaired that he could give sound judgment in consultation, invent new methods of operating, and retain those powers of collecting which enabled him to form his magnificent museum.

It never seems to have occurred to Hunter to associate any part of his ill-health with the inoculation experiment of 1767; indeed, he says expressly: "It would appear that some parts of the body are much less susceptible of the lues venerea than others; and,

not only so, but many parts as far as we know are not susceptible of it at all. For we have not yet had every part of the body affected; we have not seen the brain affected." How great, therefore, would have been his joy if his cerebral cortex could have looked down upon the great basal ganglia of his brain and recognised that

[Copyright, Wellcome Historical Medical Museum.]

FIG. 4.—Hunter's body being removed from St. George's Hospital in Mrs. Hunter's sedan chair with his chariot following behind. Note the two magpies, one on and one over the carriage, "one for sorrow, two for joy."

parts of them were suffering from the effects of the venom which he had himself introduced into his system so many years before. We look upon him as a martyr to science; he would rather have considered that the fresh knowledge was worth the penalty he paid to gain it. It is marvellous to us that he could accomplish so much, crippled as he was mentally and physically.

HUNTER BEING DEAD YET SPEAKETH.

Whilst praising John Hunter and his pupils for what has been done in the past, it is the duty of the orator to point to the influence of his teaching on the present generation of surgeons and to call attention to any outstanding work which may have been executed since the last oration was delivered in his honour. His spirit still lives and exerts its influence upon those of the younger generation of surgeons who are endowed with a portion of his originality of thought and action stimulating them to attack and advance along old lines which many had long since abandoned as useless.

THE HEART SUBDUED TO THE HAND OF THE SURGEON.

Sir Lauder Brunton, in the year 1902, suggested the possibility of treating mitral stenosis by surgical methods. He had already performed some preliminary experiments in the dead-house and upon animals, but ill-health and the generally expressed feeling which is always against any new operation involving great risk to life prevented him from carrying his design into execution upon the human subject. Nothing further was done in this country, although it had long been known to physiologists that the healthy mammalian heart could be handled with impunity, whilst

surgeons had repeatedly sutured cardiac wounds. At any rate, nothing *was* done, and it was left to Prof. Elliott C. Cutler, of the Western Reserve University at Cleveland, with the help of Dr. S. A. Levine and Dr. Claude S. Beck, to subdue the diseased human heart to the hand of the surgeon. Lately, whilst visiting the United States, I had the good fortune to make the acquaintance of Prof. Cutler and to see him operate on a dog. As the original idea was put forward by Sir Lauder Brunton, the lineal successor of Harvey at St. Bartholomew's Hospital, we must regret that it did not bear fruit there. But no one who knows Prof. Cutler, young, generous, enthusiastic, painstaking, and scientific, will grudge him the laurels he has won by his brilliant and successful operation, and all wish him godspeed in what we hope will be a long and prosperous career.

NECROLOGY.

The terms of the trust, Sir, demand of me the melancholy duty that I should draw your attention for a few moments to the losses which British surgery has sustained since the last oration was delivered. Death has been busy in our ranks during the last two years. Very noticeable is the gap left by the departure of Sir William Macewen whilst still in the full exercise of his mental and physical powers. A surgeon of such originality that he is worthy to be placed amongst the greatest of his own century. A pioneer in the surgery of the brain, in the surgery of the lung, and in the study of the infective inflammations of bone. His name seems likely to be handed down to future generations by that operation for the cure of knock-knee which should become less and less frequent as rickets becomes more rare under the influence of a better hygiene during childhood.

The name of Sir Frederick Treves will live long in the history of England. To us he appeared as a good anatomist, a fine abdominal surgeon, a fluent writer of interesting books, and a travelled gentleman. By his prompt action in an unparalleled crisis he showed himself master of the greatest attribute of a surgeon—the ability to take upon himself infinite responsibility mindful of the Hippocratic maxim that time is urgent, experience deceitful, and judgment difficult.

Mr. W. H. A. Jacobson, "the gentle cynic," and the author of the first satisfactory text-book on operative surgery in the English language, abandoned his profession at the height of his reputation, taking with him the sympathy of all his colleagues and friends.

What shall be said of Mr. S. G. Shattock—the humble-minded disciple of John Hunter, whose name he venerated and whose methods he copied, striving faithfully and zealously to advance and improve the knowledge of morbid anatomy in which, like his Master, he excelled beyond his fellows? Very few are permitted to gain the confidence, the esteem, and the affection of a whole profession. Shattock did so because he was truly the helper and adviser of all who sought him.

Three of our colleagues on the Council of this College have left us since you, Sir, delivered the last oration in 1923—Sir William Thorburn, Sir Charles Ryall, and Mr. W. Harrison Cripps.

Sir William Thorburn after an arduous and useful life at Manchester, where he did much to advance the surgery of the spine, saddened by domestic affliction, the direct outcome of the war, had just settled in London and was looking forward to a period of leisure when death seized him.

Sir Charles Ryall we miss because he was as genial as he was trustworthy in all matters committed to his charge, and to him the Cancer Hospital owes much.

Mr. Harrison Cripps possessed talents which—when combined as they were in him—are rare amongst us, first-rate business capacity, great powers of administration, and high surgical skill. He spoke but rarely at our meetings, yet his opinions always carried weight and his views usually prevailed.

Nor must I omit to mention those who worthily maintained the position of surgery in the provinces and whose loss we deplore: Mr. G. P. Newbold ;

Mr. R. A. Bickersteth, of virtuous father virtuous son ; and Mr. George Heaton, the first two of Liverpool, the last of Birmingham. All pupils of my own.

CONCLUSION.

My task, Sir, is ended, and in bringing it to a conclusion I would ask you to remember that if Hunter with the knowledge and means at his command seems to us to-day to walk haltingly or even often to have gone astray, shall not we seem to have done the same to those who read our story a hundred years hence? It is one of the lessons of history that each age steps on the shoulders of the ages that have gone before and that the value of each generation is in great part a debt to its forerunners.

The oration finished with the exhibition of a series of lantern slides, four of which are here reproduced, made from water-colour sketches for Jesse Foot who wrote a scurrilous life of John Hunter. They show Hunter as he appeared to his contemporaries, and not as he was idealised by Sir Joshua Reynolds in his well-known portrait. Sir D'Arcy Power stated that he was indebted to his friend, Mr. C. J. S. Thompson, for permission to show the drawings which are contained in a volume in the possession of the Wellcome Historical Museum.

THE DIAGNOSIS OF UNILATERAL PHRENIC NERVE PARALYSIS.

AN IMPORTANT POINT IN MEDIASTINAL
LOCALISATION.

BY SIR CHARLTON BRISCOE, BART., M.D.,
F.R.C.P. LOND.,

PHYSICIAN TO KING'S COLLEGE HOSPITAL.

THE diaphragm belongs by origin to the muscles of the neck, but in the process of the evolution of the body it has shifted its position to a lower plane while still retaining its original nerve-supply. The shift has thus entailed the development of a phrenic nerve trunk on each side, which in proportion to its length is liable to become involved in lesions of neighbouring organs.

From the frequency with which these neighbours are affected by disease we might expect unilateral phrenic paralysis to be a not uncommon event, a view which seems confirmed by the fact that 15 of the 30 cases on which this paper is based have been observed in the last 12 months. Yet, in general, the clinical diagnosis is one not often made, and the literature on the subject is scanty and unsatisfying, facts which suggest the existence of inherent difficulties such as have led to the condition being overlooked. Indeed, these difficulties are very real. One is obvious and ever present. We have not to deal with a simple muscle exerting a straightforward easily ascertained action upon fixed points, but with a double sheet of complex fibres hidden deep in the body, the actions of which are far from simple, and only to be recognised by effects which are not only for the most part indirectly produced, but are always complicated by the interfering action of other muscles. Other difficulties will appear in the course of this paper.

Literature.

The text-books in general state that when the whole diaphragm is paralysed there ensues overaction of the intercostals and of the accessory muscles of respiration, together with inspiratory recession of the epigastrium. When one half only is affected there may be limited propulsion of the epigastrium on the affected side. Oppenheim¹ states that Litten's sign may be absent and the respiratory sounds faint, and concludes that unilateral paralysis is difficult to detect. Nesbit² diagnosed a case as paralysis of the left phrenic nerve. At first there were over expansion and increased resonance of the left side of the chest. Later, dullness appeared over the root of the left lung in front. The case was one, however, of gradual

obstruction of the bronchi, and the post-mortem report lacks mention of involvement of the phrenic nerve. Monographs on mediastinal tumours contain but little mention of phrenic paralysis, and give no description at all of the resultant physical signs. Morrison Davies³ has recommended division of the phrenic nerve on one side for persistent infections of the corresponding lower lobe because it controls the expansion of this area. He does not, however, describe the physical signs which result from the operation. Schroeder and Green⁴ have produced the most important monograph on the subject. They describe a case in which the left phrenic nerve was torn during the removal of a tumour from the neck. After some temporary discomfort and increased rate of respiration the man was able to resume work at the end of three weeks. Nothing is said about the physical signs which resulted from the torn nerve, save that some dullness developed at the lower part of the left chest. These authors then made experiments on dogs, cutting one or both nerves. Their research was chiefly concerned with degeneration of the diaphragm. They gave a long survey of the literature of phrenic nerve lesions, records of which were inconclusive: they concluded that in man and most mammals a fringe of diaphragm is supplied by some of the lower intercostal nerves, but that this supply is not effective as a substitute for the innervation by the phrenics. Their most important conclusion was that division of one phrenic nerve is not necessarily fatal.

In the Arris and Gale lecture, 1919, on Collapse of the Lungs,⁵ I described some experiments carried out on rabbits. In these the animal was killed, generally under prolonged anaesthesia, at varying periods after section of the phrenic nerve on one side. Under these circumstances areas of deflation were found in both lungs, but were more marked on the homo-lateral side. The parts affected were (1) the apices of both lower lobes, (2) the adjacent parts of the upper lobes, (3) the free margins of the lower and to a less extent of the upper lobes. Section of the right nerve produced a greater effect than section of the left. The collapse was more marked at the end of three days than at later periods.

Clinical Material.

The material on which this communication is based consists of a series of 30 cases, 21 of which came to post mortem; 15 have been seen in the last 12 months. In six there was a history of syphilis. In these no complicating condition could be found in the neck, mediastinum, or abdomen, and four of them have recovered. A seventh was a case of aneurysm, confirmed post mortem. In three cases the condition was due to primary glandular enlargement. Two came to post mortem. In 12 patients there was a primary growth in the neighbourhood of the root of the lung. Ten were verified post mortem, the thymus being the probable starting-point of the growth in two. The other two died after leaving hospital. In seven other instances the condition was due to malignant deposits secondary to primary growth elsewhere. All came to post mortem. In the remaining case, a boy who recovered, the lesion was probably due to tuberculous mediastinal glands.

Anatomy of the Phrenic Nerves.

The phrenic nerve derives its fibres from the anterior primary divisions of the spinal nerves, mainly and constantly from the fourth, and variably from the third and fifth cervical. It has a fairly constant communication with the nerve to the subclavius (C5, C6), from which nerve further fibres may be derived. It descends usually in front of, but sometimes embedded in, the substance of the anterior scalene muscle and thence, passing downwards between the subclavian artery behind and the subclavian vein in front, gains the mediastinum, where it is closely related to the subclavian artery. So far the course and relations of the right and left phrenic nerves are similar. In this the first part of its course I have found the nerve involved and constricted by

lymph glands in seven cases, four of which were on the left side.

In the mediastinum the relations differ on the two sides of the body. On the right side the nerve comes into close relationship with the innominate vein and superior vena cava, and follows the latter until the reflection of the pericardium is encountered. In the upper part of its intrathoracic course the nerve lies about one-third of an inch in front of the right lung. The right vagus is not a near relation. On the left side the phrenic enters the mediastinum in front of the left subclavian artery, and, passing downwards in front of the arch of the aorta, gains the pericardium. In this part of its course the nerve is in close relationship to the left innominate vein for about half an inch, and to the aorta for about 2 inches. The left vagus, prior to giving off the recurrent laryngeal nerve, crosses posteriorly to, and then lies half an inch to the inner side of, the phrenic. Between the arch of the aorta and the pericardium the root of the lung is in an immediate posterior relation to the nerve. The remains of the thymus are also near the nerve and anterior to it. The main mass of mediastinal lymph glands lies behind the arch of the aorta and internal to the phrenic nerves. In this part of its course I have found the right phrenic nerve implicated in four instances, and the left nerve in six. The superior vena cava on the right and the vagus on the left are liable to be involved at the same time.

On the pericardium the nerves are embedded in a fibrous sheath on the outer surface of the pericardium between it and the pleura. The left nerve is on a plane somewhat anterior to that of the right. Near the diaphragm they frequently branch into posterior and antero-lateral branches, and the latter subdivide to supply the anterior and lateral parts of the diaphragm arising from the eleventh and anterior parts of the ribs. In this region each nerve was found to be involved in two cases. The lesion generally arises from an implanted secondary neoplastic growth, or from the invasion by such growth of an adhesion extending from the lower and anterior part of the mediastinal surface of the upper middle or lower lobes. In several cases the nerve has been affected at more than one point.

Diagnostic Criteria.

During the progress of investigation a certain group of clinical signs, to be described in a subsequent paragraph, came to be regarded as pointing to unilateral phrenic paralysis. The diagnosis was not considered established unless these signs were confirmed by: (a) post-mortem evidence of a point of pressure on the nerve combined with macro- and microscopic change in the diaphragm; or (b) X ray evidence of defective movement of one side of the diaphragm at a time when the presence of any complicating factor, such as pleural effusion, could be excluded. Of 20 cases which showed this limitation of movement on X ray examination, 13 were subsequently confirmed post mortem.

Concerning X Ray Examinations.—Verification of the diagnosis by X ray or post-mortem examination appears simple, but there are points of difficulty in connexion with each, and these are of such importance that they must be dealt with in detail. Most patients with phrenic paralysis are too ill for prolonged examination, and cannot tolerate the supine posture for any length of observation. The X ray investigator does not make a sufficiently detailed examination of the diaphragm unless especially requested to do so. Even when his attention is focused on this point the outline of the diaphragm may be far from clear. On deflation the lung becomes somewhat opaque to X rays, both in and out of the body, and this obscures the view and may give rise to a false report of the presence of fluid.

The typical appearance is well described by Woodburn Morison.⁶ The diagnostic feature is the "reversed movement" of the paralysed half of the diaphragm, which not only does not descend, but may even ascend, while the sound half is contracting.

Morison draws attention to the fact that this is best seen during quiet breathing.

The appearance of a "high diaphragm," often considered typical, is not by any means always present, and slight elevation, when it does occur, can readily pass for a normal difference in height. If the patient be requested to take a deep breath the abnormal movement may be obscured, either by the excessive contraction of the sound side dragging down the paralysed side, or possibly by nervous impulses of greater intensity breaking through the nerve block. Or, again, since the conscious deep respiration following the request will be of thoracic type, neither half of the diaphragm may be depressed. Reports such as "some restriction of movement," "scarcely any movement," "slight movement" have been given for cases in which the clinical diagnosis was clear during life and confirmed post mortem.

In several of my cases another sign of considerable interest has been observed—namely, late inspiratory displacement of the mediastinum to the unaffected side. A further difficulty arises when the lung or diaphragm on the paralysed side is adherent to the chest wall. In this event definite diagnosis by X ray is impossible.

Concerning Post-mortem Examination.

One difficulty exists in the fact that but few of these cases die without the presence of some complication such as pleurisy, with or without effusion, bronchial obstruction, &c. In my series of 21 post-mortems only five subjects were free from some such complicating lesion. Another difficulty is the relative absence of clearly demonstrable changes in the phrenic nerve below the level of the lesion. This subject is fully dealt with later.

As the first step in the post-mortem, it is absolutely essential to obstruct the trachea, in order to prevent the usual deflation of the lungs when the thorax is opened. The trachea should be exposed in the neck and an opening made into it just large enough for the insertion of a cork. A cork is introduced, pushed just below the opening, and a stout ligature firmly tied round the trachea against the cork. The sternum and cartilages can now be removed by cutting through the diaphragm below the costal margin, lifting up the lower ribs, and cutting each costal cartilage under inspection, up to and including the second. The clavicles should then be divided at the junction of the middle and outer thirds and the inner portion removed, the first ribs cleared above carefully and divided by the saw opposite the section through the clavicle, and the whole sternum removed with the neck muscles attached. This leaves an easy and clear dissection of the phrenics.

A survey should then be made of the general position of the organs. The striking feature is the retraction of the upper lobes of the lungs in the middle line, the upper mediastinum and pericardium being left widely exposed. The tip of the lower lobe will be found in the vertical or coronal plane of the phrenic nerve, and will not be visible till the thoracic wall is pulled outwards. This lung retraction is more pronounced on the side of the paralysed nerve. The upper lobes are inflated and pale, and tend to encroach on the area occupied normally by the lower lobes. This is particularly marked in the paravertebral grooves where the upper lobes may extend as low as the fifth or sixth ribs. The lung on the affected side is smaller than its fellow. The position of the liver is frequently of interest. With right phrenic paralysis the lower border will be horizontal at right angles to the long axis of the body. With left-side paralysis the angle between the lower border and the median vertical plane will be more acute than normal. It may be reduced to some 30°. This displacement is due to the excessive and unbalanced action of the non-paralysed side, the liver being fixed to the diaphragm at the opening of the inferior vena cava. On examining the lungs after removal, the lower lobes are relatively shrunken and show areas of deflation,

marked in the paravertebral grooves, and complete at the free margins; the upper lobes, except near the intralobar fissure where the condition may resemble that in the adjacent lower lobes, look natural or more pale than normal, and are fully distended. On the whole the lungs are smaller than normal, with inflated upper lobes and partially unexpanded lower lobes.

In the diaphragm the following changes may be seen on the affected side. The colour may be normal or appear more brown and less purple than usual. The vessels may be dilated. The connective tissue fat is usually diminished in amount, this being best observed from the peritoneal surface. To the touch the muscle feels thin, and the pleura and peritoneum are found to strip too easily. When closely inspected the muscle sheet presents a plicated appearance, the individual bundles of muscle-fibres being unduly differentiated because they are more separate than normal. Differences in height have not been observed, but the length from attachment to insertion of corresponding portions of muscle on the two sides is not altered. In three patients the rather unusual condition was found of pleural fluid pressing the diaphragm down to such an extent as to make the lower surface convex. In each case this occurred on the paralysed side only.

In all cases microscopical sections of corresponding areas of muscle from the two sides were examined. Muscle from the paralysed side shows "clumping" of individual muscle-fibres, so that, instead of each being separated from its neighbour, they occur in close apposition in groups numbering up to 20. This explains the appearance of plication seen by the naked eye. The muscle striation may be defective and the number of nuclei increased. Fatty degeneration has not been observed. These changes are probably due to disuse and, up to six months' duration, do not seem to vary much in different specimens. In one specimen, probably of three years' duration, much increase of fibrous tissue had taken place, but many muscle-fibres could still be recognised. In three cases marked by progressive bronchial obstruction, in which terminal dyspnoea had been extreme, the muscle-fibres on the unaffected side were broken into squares and parallelograms, calling to mind the condition of fragmentation seen in heart muscle.

In respect of muscle changes secondary to nerve lesions Platt and Bristow⁷ state that (a) disuse atrophy is the direct result of the severance of axis-cylinders (denervation), and (b) trophic changes are dependent always on the existence of some form of irritation acting on vaso-motor and sensory axons which still retain their integrity.

The anatomical lesion affecting the nerve may be of three kinds: (1) The nerve may be completely surrounded by growth which in some instances even invades its sheath. In two of my cases the nerve tore easily in the growth. (2) It may be compressed between two enlarged glands and show an obvious constriction mark when they are separated. (3) It may be constricted or pressed out in the form of a ribbon by inflammatory fibrous tissue. Below the point of involvement the nerve trunk in some instances appeared quite normal. In others, though normal in colour, it was attenuated, while in others again it was swollen and of creamy or light yellow colour. In all cases the phrenic nerves of both sides have been sectioned and stained in the ordinary way, and in a considerable proportion the special methods for demonstrating nerve degeneration have been applied, but without revealing any startling changes. Staining by Marchi's method shows nothing abnormal except slight changes in the myelin sheath only at the point of constriction; by Weigert Pal, nothing definite; by Cajal—for nerve fibrils—nothing precise. In a transverse section stained by Van Gieson there may be seen shrinking of the nerve from the sheath, irregularity in outline of nerve fibres, defect of staining of the axis-cylinders, and some increase of nuclei of the endoneurium, but all these changes are slight and debatable, especially in view of the "artefacts"

which may result from post-mortem changes and handling.

Pressure Effects.

The absence of more definite pathological lesions in the nerves might appear to throw doubt on the evidence on which my thesis is based. However, there seems to be little doubt that pressure upon a nerve may cause complete paralysis without producing histological changes such as we can, at present, recognise. In two of my cases of this series the lesions involving the phrenic nerve also involved the vagus central to the origin of the recurrent laryngeal nerve. That the left vocal cords of these patients were paralysed admits of no doubt. Post mortem the laryngeal muscles and recurrent laryngeal nerves showed exactly the same slight changes as the diaphragm and phrenic nerves. Dr. Wilfred Harris allows me to state that in a case of median nerve

The whole question of the effects produced by pressure on nerves still remains to be worked out. There is, however, ample justification for assuming (a) that pressure sufficient to paralyse a nerve may readily occur in the body; (b) that such pressure need cause but little objective change in the nerve; (c) that degenerative changes are not demonstrable in the muscle at an early date; and (d) that nerve-block may be partial.¹²

Physical Signs of Phrenic Paralysis.

The physical signs will be dealt with in the order of importance. The examination should be made with the patient sitting and the back inclined at an angle of 45°, the head resting on a pillow. He should not be allowed to talk. A skin pencil should be used to mark the extent of resonance. When examining the back he should draw the knees up and rest the elbows on the knees and chin on the palms. The whole examination

FIG. 1.

Paralysis of left phrenic.

FIG. 2.

Paralysis of right phrenic.

paralysis due to a fibrous band full movement followed within 24 hours of the operation which relieved the pressure. Similarly, though for a time the paralysis may be marked, the rapid recovery which may be seen in crutch palsy or Saturday night paralysis negatives the idea that loss of function is necessarily accompanied by structural changes which can be demonstrated. Buzzard and Greenfield,⁸ discussing long-continued pressure, write, "In the earlier stages the condition is one of loss of function without destruction of axis-cylinders." Oppenheim,⁹ quoting Dejerine and Bernhardt, states that organic changes at the point of moderate pressure are slight and limited to the myelin. If, however, compression is severe or prolonged changes may extend to the whole distal section of the nerve. They note, however, that the rapidity with which recovery takes place when a nerve is freed from compression by callus or bone shows that these organic changes are not always present. The prevalent teaching, in fact, indicates that the relative absence of histological nerve change post mortem does not invalidate a diagnosis of paralysis during life. With regard to the degree of pressure necessary to prevent the conduction of a stimulus, very different results have been given by Ducceschi,¹⁰ Meak and Leaper.¹¹

In some experiments performed in 1908 I found that three minims of 5 per cent. carbolic acid or 10 per cent. formalin injected into the pleural cavity, or applied to the phrenic in the neck of a rabbit, paralysed the diaphragm of that side, inhibiting the normal respiratory impulse. Electrical stimulation of the phrenic nerve in the neck above the block evoked contraction of the diaphragm, which again did not contract when the electrical stimulation ceased. Other motor nerves behaved similarly. These observations suggest that nerve-block may be partial, and that slight degrees of pressure which can obstruct weak impulses may prove ineffective against the passage of impulses from stronger stimuli.

should be gone through with quiet, natural respiration before any deeper breathing is requested. The signs described are detected in this stage—deep breathing may reveal very little abnormal.

1. *Manubrial Lack of Resonance.*—This will be found to be increased. The normal pleura is attached along a line extending from the central point of the junction of the manubrium and gladiolus to a point behind the sterno-clavicular articulation. The lack of resonance extends outwards in planes roughly parallel to this line; the lower end advances somewhat more than the upper, so that when the junction of the inner and middle thirds of the clavicle is not resonant the inner border of the resonance is vertical and parallel to the middle line of the sternum, meeting the deep cardiac dullness. When the left phrenic is paralysed the left side only is defective. When the right is affected, both sides are liable to be deficient in resonance. Such "dullness" is often ascribed to enlarged mediastinal glands which may not be found at the post-mortem. Regarded as lack of resonance, caused by retraction of the lung border, the findings are more intelligible. When examined after a deep breath the areas of lack of resonance will diminish to extend again when quiet breathing is resumed.

The structures which, when abnormal, can by pressure prevent the expanded lung filling the pleura, are the thymus, aorta and deep mediastinal glands, pleural adhesions, and possibly affections of the oesophagus. There are few glands between these structures, and the manubrium and these are but seldom affected. In very few instances can the above pathological conditions produce by pressure a lack of resonance which returns with a deep breath. When both phrenic nerves are involved, the extreme thoracic effort produces a further expansion of the upper lobes and renders this area resonant.

2. *Lower Level of Pulmonary Resonance.*—This is raised. Posteriorly it may extend as high as the seventh rib in the scapular line. When the left

phrenic alone is involved the elevation is likely to be on the left side only. With right phrenic involvement the level on the left may be found as high as the ninth and on the right a little higher—e.g., eighth. Anteriorly on the right side the level may be as high as the third space. If the level is marked out all round it will be found to rise in the posterior axillary line and again between the nipple line and the sternum. The explanation of the first-mentioned elevation is that at this point the muscle-fibres of the diaphragm are longer than elsewhere, and when paralysed relax to a greater extent. Of the second, that the crus exerts its direct pull towards this point on the chest wall, and when this tension is eliminated the anterior paralysed portion of the diaphragm is raised out of proportion to the adjacent and outer part which is less influenced normally by the crus. On the left side the stomach resonance renders percussion in the axilla uncertain. The spleen may occasionally be made out to be raised, as indicated by a rise of the normal level of dullness.

3. *Type of Breathing.*—Normal inspiration is effected by descent of the diaphragm—the so-called “abdominal” element—with raising and expansion of the bony thorax—the so-called “thoracic” element. The relative proportions in which these two elements come into action varies in different individuals, and it is in general true that the more conscious the breathing the more the thoracic element is called into play, also the older the patient the less the thorax is used. The value of deductions as to the relative proportions of the thoracic and abdominal breathing in any case will largely depend on the observer's experience, but it is an invariable rule that conclusions should not be drawn in the early stages of examination, when the patient's attention is more or less turned to his breathing, or from a voluntary forced inspiration. The last will certainly be almost purely thoracic.

With inspiratory descent of the diaphragm the epigastrium should be pushed forward. When both phrenic nerves are paralysed conditions are reversed, and epigastric recession is usually very marked. With unilateral paralysis matters are less simple. In most cases the epigastrium is protruded, but frequently with unsteady or intermittent force. In some normal protrusion is reduced and forms a contrast with the simultaneous thoracic action, which is increased. In a few cases there has been a clear difference of propulsion in the two sides of the epigastrium in favour of the sound side. A test may be applied by laying the hand on the umbilicus, and asking the patient to press it up. With bilateral paralysis this is impossible, but with unilateral paralysis it can be accomplished, and with a considerable amount of force.

The diaphragm, in conformity with the general law governing muscle, acts best when its fibres are under tension. Tension is provided by intra-abdominal pressure and is reduced when the abdominal wall is lax.¹³ When such tension is absent the tendency to epigastric recession is greater, as was well shown in one of my cases which developed ascites. The degree of epigastric recession varied with the quantity of fluid, being marked after tapping and disappearing again as fluid reaccumulated. Recession is marked when general wasting has occurred.

With regard to the thoracic element of inspiration, in cases where both phrenic nerves are involved and dyspnoea becomes extreme, thoracic expansion is increased to a very marked degree. In such cases the upper lobes are markedly over-distended and the manubrium becomes resonant, while the signs in the lower part of the chest become more marked.

With unilateral paralysis thoracic respiration is generally increased. Comparison of the two sides of the chest does not always show greater movement on the affected side, indeed the reverse may occur. In a number of these cases thoracic movement is peculiar, inasmuch as the chest is held elevated by the scalenes and expanded by the intercostals, neither of which relax to the usual degree during expiration. These patients are apt to suffer from persistent pain in the

shoulder and down the arm. In three individuals with unilateral paralysis who lived for a considerable period thoracic movement on the sound side developed to such an extent that with each inspiration the chest came forward in an arc, the centre of which appeared to lie somewhat outside the opposite axilla. The resultant “swinging” chest is a remarkable object.

4. *Auscultation* reveals a deficient inspiratory murmur on the paralysed side. The expiratory murmur is often of equal length and intensity on the two sides of the chest. The breath sounds may be abnormal, having a puerile or broncho-vesicular character. Voice sounds may be altered, and if examined before a deep breath be taken, ægophony may usually be heard at the lower level of the pulmonary resonance. With a deep breath everything may be altered, and the variations seen on different occasions, even in the same individuals, are remarkable. The differences are readily accounted for by variations in the degree of deflation and air exchange.

5. *Cardiac Dullness.*—Owing to the lung retraction this is increased on the affected side, the abnormal extension being decreased by a deep breath. This is apt to lead to the conclusion that the heart is displaced or enlarged, conditions which can be shown by X rays not to exist.

6. *Cardiac Impulse.*—Again, owing to lung retraction the area over which pulsation is felt may be unduly wide and lead to false impressions. In left-sided paralysis the apex beat may be displaced outwards, and may also be rotated upwards to the fifth rib or fourth space. In right-sided paralysis pulsation, the auricular origin of which can be demonstrated by the polygraph, may appear to the right of the sternum. The apex beat is not displaced unless dyspnoea is severe, in which case it may be displaced down to the sixth or even seventh space, and slightly outwards, but may be obscured by the usual simultaneous over-inflation of the left upper lobe. This is due to overaction on the part of the sound left side of the diaphragm.

7. *Differences in the Movement of the Costal Margin.*—In quiet breathing there will frequently be no difference on the two sides. If a difference is present the costal margin of the paralysed will move outward, more than the normal side. A forced inspiration may either accentuate or diminish the differences according to the proportionate activity of the thorax and diaphragm. Hoover¹⁴ lays great stress on the movement of the lower thoracic margin in cases of pleural effusion, and states that the more horizontal the diaphragm the greater the indrawing of the costal margin and vice versa.

8. *Tracheal Displacement.*—The trachea may be situated mesially or may be displaced, either away from or towards the affected side, whichever that may be.

It has been noted that the signs are the more marked when the right side of the diaphragm is affected. This is no doubt due to the presence of more muscle in the right crus of the diaphragm, the force of which is expended in the postero-anterior direction rather than elsewhere. It tends to form a band between the spine and meso-lateral costal margin, and will be scarcely displaced to the right side by the weaker fibres arising from the ribs in the right axilla. The left crus is much less developed, and will be proportionately less able to resist the corresponding lateral pull. Accordingly, when the right half of the diaphragm is inoperative and this antero-posterior force is in abeyance, the fibres from the left costal margin will more easily displace the central tendon and structures attached to the left.

Arising from the diaphragm along this line of traction is the right side of the pericardium, which is especially reinforced here by fibrous tissue, and is extended upwards to the cervical fascia through the superior cava and mediastinal fascial coverings. This, when controlled by the right crus, must tend to steady the mediastinum and prevent displacement. On the left side the pericardium as a ligament is

practically of no consequence. There will accordingly be a greater tendency to pull the heart and mediastinum to the left when the right side is paralysed than to the right when the left phrenic is affected. The absence on the left side of a distending force on the muscle fibres, such as is constantly exerted by the liver on the right side, must render the left half of the diaphragm normally less efficient than the right, and accordingly the effects of the left-sided paresis less severe than that of paresis of the right side. I think these are reasons for the lesser degree of discomfort when the left side is paralysed.

Symptoms of Phrenic Paralysis.

This communication is not concerned with the general signs and symptoms of mediastinal or other lesions. There are, however, three symptoms which deserve mention because they are directly connected with the phrenic paralysis.

1. *Pain.*—At the onset of paralysis there may be a history of acute pain on the affected side, either over the shoulder and down the arm, or in the neck or thorax. The pain is accentuated on pressure over the scalene and intercostals, and is due to undue stress and fatigue of these muscles.¹⁵ Similar pain may occur behind the sternum owing to the stress of the triangularis sterni and transversalis abdominis, expiratory muscles which also become tender to pressure. These pains are particularly connected with the onset of phrenic paralysis because of the sudden call on these muscles for extra effort to compensate for the diaphragmatic defect, but later they may accompany extra effort due to exertion.

2. *Respiratory Distress.*—Dyspnoea is apt to be well marked at the onset of paralysis, but then diminishes and reaches a stationary condition after 10 or 14 days. As might be expected, this dyspnoea of onset is absent in patients in whom the paralysed half of the diaphragm was previously anchored to the chest wall by adhesions, as was noted in three of my cases. There is considerable difference in the degree of dyspnoea experienced by different individuals. Some can walk about easily and only become distressed on exertion, whereas others can hardly walk at all owing to dyspnoea and pain of the type mentioned. In general the younger the individual the less the distress. In older people the disability varies with the capacity to expand the thorax—in other words, it is proportional to the amount of senile fixation of the bony framework.

3. *Posture.*—When in bed patients with unilateral phrenic paralysis prefer to be slightly propped up or to lie on the affected side. Even those who are able to walk without undue distress become uncomfortable when lying on the sound side. It can be shown by X ray examination that when the body is in the lateral position it is normal for the lower half of the diaphragm to become relatively quiescent, throwing extra work on the upper half; hence when the latter is paralysed distress is bound to be felt. The work of Adams and Pillsbury¹⁶ supports this view.

Summary and Conclusions.

A syndrome recognisable clinically has been described the signs of which are due partly to defective action of one-half of the diaphragm, and partly to the resultant incomplete expansion of the lungs. In this series of cases the causal factor has been pressure on the phrenic nerve of one side. This syndrome is important as assisting in the diagnosis and localisation of intra-thoracic lesions. Too much stress cannot be laid on the importance of making the physical examination during quiet and natural breathing.

I have to thank my colleagues for allowing me to investigate the cases under their care, and Prof. Frazer of St. Bartholomew's Hospital for a similar courtesy in one instance. I am also greatly indebted to Dr. Wiltshire for his help and criticism of this paper, to Dr. Greenfield and Dr. da Fano for advice on the microscopic technique, and to Mr. S. Mitchell for the preparation of the sections.

NOTE ON A CASE OF PARENTERIC FEVER CAUSED BY *B. COLUMBENSIS CASTELLANI.*

BY H. N. C. VAN GEYZEL KELAART,
M.R.C.S. ENG.,
RESIDENT MEDICAL OFFICER, ITALIAN HOSPITAL, LONDON.

FOR some years it has been noted by various observers, and principally by Castellani, Chalmers, Balfour, and Archibald, that in tropical and sub-tropical zones, and occasionally also in temperate zones, there occur a comparatively large number of cases clinically somewhat resembling typhoid or paratyphoid, in which, however, the bacteriological examinations for typhoid and paratyphoid are constantly negative, while other organisms are found which are in all probability the true aetiological agents.

Castellani has introduced the term *parenteric* to indicate these cases, and he has suggested the following classification of intestinal fevers: 1. Fevers due to *B. typhosus* Eberth, *B. paratyphosus* A Schottmüller, *B. paratyphosus* B Schottmüller, *B. paratyphosus* C Hirshfeld = enteric. 2. Fevers due to intestinal bacilli which differ from typhoid and paratyphoid bacilli = parenteric. To cover both groups of fevers, enteric and parenteric, he introduced the term "enteroid" (enteroidea).

The best known types of parenteric are *B. asiaticus* parenteric and *B. columbensis* parenteric, both first described by Castellani. The former has recently been thoroughly investigated in Egypt by Khaled.

Clinical Record.

It may be of interest to put on record a case of *B. columbensis* parenteric which I had the opportunity of investigating at the Italian Hospital, London, a few months ago:—

Miss N. B., aged 26, sister-in-charge of a medical ward. Nothing important in her past medical history; never had typhoid. Has been residing in London since March, 1923; always in good health. At the beginning of May, 1924, began to feel somewhat tired, complained of headache; had small nasal hæmorrhage. From the 9th on she took her temperature daily, morning and evening; on the 9th in the evening it was 100°, on the 14th, 102°. The temperature in the early morning varied according to her statements from 99° to 100°. She continued working until the 15th, when, feeling very bad, she reported sick to the matron, and I saw

Alk = Acid then alkaline; Gt = general turbidity; Vs = very slight; 0 = negative result—viz., neither acid nor gas in sugar media, non-production of indol, non-liquefaction of gelatin or serum as the case may be; + = positive result.

Remarks.—Certain strains of *E. columbensis*, serologically typical, ferment dextrin; certain strains of *E. asiaticus*, serologically typical, have no action on dextrin, raffinose, and sorbitol.

her. She was feeling very tired and complained of severe headache and slight abdominal discomfort and constipation. Tongue very coated; nothing worth noting at the examination of the chest; abdomen somewhat distended, no roseola; spleen and liver not palpable; no albumin or sugar in the urine. She was put on liquid diet and so-called intestinal disinfectants. The temperature, at first subcontinuous then tending to be intermittent, lasted two weeks more (probably three weeks in all). No complications arose.

Bacteriological Examinations.—The blood was examined by serological tests during the fever and after defervescence. The agglutination was always completely negative for *B. typhosus*, *B. paratyphosus* A, *B. paratyphosus* B, and *B. paratyphosus* C, also for *M. melitensis* and *M. parameitensis*, also for *B. asiaticus* (variety *mobilis* and variety *immobilis*); the microscopical examination of films for malaria was negative. The blood agglutinated *B. columbensis* up to a dilution of 1:160. Further agglutination tests showed that the agglutination gradually decreased until, on Sept. 14th, it was 1:40.

Stools.—No typhoid or paratyphoid bacilli found; a bacillus was grown with all the characters of *B. columbensis*. It was agglutinated by the patient's blood in slightly higher dilutions than the laboratory strains of *B. columbensis*; it was not agglutinated by typhoid or paratyphoid sera. Highly agglutinated, more than 1: 600, by *B. columbensis* serum kindly supplied by Dr. Mackenzie Douglas.

Remarks on the Strain of B. columbensis Isolated.—The principal characters of this strain isolated from the stools are as follows : It is a motile, Gram-negative bacillus easily stained by the usual aniline dyes. Lactose is not fermented; this is interesting in view of the statement made by Castellani and others that certain strains of this bacillus when recently isolated have an inconstant action on lactose, generally not fermenting it, but occasionally doing so and producing at times a slight amount of gas. So far my strain has been always negative as regards lactose. The action of my strain on other carbohydrates is as follows :—

Glucose: acid and gas. Maltose: acid and gas. Saccharose: no change. Dulcitol: no change. Arabinose: acid and gas. Glycerine: acid and gas. Lævulose: acid and gas. Galactose: acid and gas. Raffinose: no change. Mannitol: no change. Inositol: no change. Dextrine: no change.

In litmus milk there is a slight acidity at first, then the medium becomes slightly alkaline. My strain produced indol, and the Voges-Prosk reaction was negative. Gelatin and serum did not become liquefied. In broth and peptone water it produced a general turbidity. Serologically the strain isolated is identical with the laboratory strains; it is not agglutinated by typhoid and paratyphoid sera, it is agglutinated in high dilution by columbensis serum.

The biochemical characters of *B. columbensis* are recorded in the table, together with the biochemical characters of a few other intestinal bacilli. A complete table of intestinal bacilli may be found in Castellani and Chalmers's "Manual of Tropical Medicine," p. 944.

Résumé and Conclusions.

The patient developed a fever which lasted approximately three weeks. All the serological reactions for typhoid and paratyphoid were constantly negative as well as the bacteriological examination of the stools for the same germs. Instead the blood showed marked agglutination (1:160) for *B. columbensis*, which has gradually decreased since the fever ceased. From the stools a bacillus was grown with the characteristics of *B. columbensis*; it was well agglutinated by the patient's blood in slightly higher dilution than the laboratory strains.

In my opinion the case I have briefly described is in all probability a case of "parenteric fever" due to *B. columbensis* Castellani. This type of parenteric is also known as "febris columbensis."

OBSERVATIONS UPON THE EFFECT OF AN ANTISERUM UPON CANCER CELLS IN VITRO.

BY THOMAS LUMSDEN, M.D. ABERD.

(From the Department of Experimental Pathology,
Lister Institute.)

In 1906 Ehrlich¹ observed that a mouse tumour inoculated into a rat survived and increased in size for some days and then died out. Thereafter the rat was immune to the tumour concerned. This observation has been confirmed by many workers. The serum of a rat thus immunised has no appreciable curative effect when injected into a mouse bearing the tumour. Using the method of tissue culture, previously described,² I found that the mouse cancer cells may retain their activity in such a serum for a month or more, which indicates that the latter must contain few if any antibodies. It seemed possible, however, that by repeating the inoculations into the rat an effective amount of antibodies might be produced. I was encouraged to pursue this idea by the fact observed by Ledingham³ in 1914, that a potent anti-platelet serum was produced in the rabbit only after repeated inoculations of guinea-pig blood platelets. Several interesting papers on immunity to cancer and reviews of the literature up to 1912 are to be found in the third and fifth scientific reports of the Imperial Cancer Research Laboratory. Since that date no fresh facts of outstanding importance have been forthcoming on this subject.

Method.—A mouse mammary carcinoma (M 63 of the Imperial Cancer Research Laboratory) was dissected out carefully, with rigid aseptic precautions, washed in normal saline, and finely divided up with scissors. Of this 0.1 c.cm. was inoculated subcutaneously into two rats. Tumours appeared and grew for 10–12 days and were then reabsorbed. Thereafter, 1 c.cm. of similar tumour material was injected into the peritoneal cavity of each rat, weekly for eight weeks.

Seven days after the last injection in Rat 1, and three days after in Rat 2, the serum of the rats was collected and stored in sealed capillary tubes made of "resistance" glass. An anti-rat-cancer serum was similarly made from two rabbits. Cancer cells, various normal tissues from young animals, and both of these together were then cultivated in the antisera, with controls in normal rat or rabbit serum.

Experimental Observations.

1. In the serum of Rabbit 1 six cultures of rat cancer were set up with controls in normal rabbit serum. All the controls showed the usual amount of migration. In the immunised rabbit serum a precipitate appeared and in every instance the cancer cells died within 24 hours. No migration occurred.

2. In the serum of Rat 1 four cultures of cancer (M 63) were set up, controlled by six fragments of the same tumour in normal rat serum. In the former precipitation occurred in the serum and death of the tissue rapidly took place, as evidenced by complete absence of migration, and by fatty degeneration of the original fragment. All the controls grew vigorously; of these two were selected and were re-fed on the third day (when showing very active migration) with the

serum of the immunised Rat 1. The migrating cells were found to be completely lysed within six hours. On the fifth day two other controls were similarly treated with a like result. (Figs. 1 and 2.)

3. In order to determine whether the lethal factor in this serum was anti-mouse or anti-cancer bodies, a series of 16 cultures were set up as follows: In the

serum of Rat 1, two cultures of cancer alone, one of cancer and heart symbiotically, one of cancer and kidney, one of cancer and spleen; similar tissues were set up in normal rat serum as controls. Cultures of mouse heart, kidney, and spleen were also set up alone in each serum. The pH of the serum was in all cases roughly 7.6. All the cancer fragments in the immunised rat's serum were dead within 24 hours, whereas the normal young mouse tissues survived. Thus the heart muscle continued to beat for several days

and to grow alongside the dead fragment of cancer. In the controls in normal rat serum all the normal tissues grew and the cancer fragments showed very active migration. After some days certain of the control cultures in which both cancer and heart

FIG. 1.

³ Ledingham: THE LANCET, 1914, i., 1673.

muscle were active, were fed with the immunised rat serum—photographs being taken before and after. In every instance the migrating cancer cells were completely lysed; the normal tissue continued to grow.

4. With the serum of immunised Rat 2 further series of cultures similar to those mentioned above were set up, with entirely confirmatory results. The normal tissues used were young mouse kidney, salivary gland, and heart. This serum (Rat 2) did not, however, show a precipitate, but some (? lipid) substance separated out in a fine scum at the interface between the drop of serum and the air in every case where mouse cancer was present. This did not occur in the controls. The interface appeared wrinkled and not unlike a certain variety of non-transparent "frosted" glass.

Remarks and Conclusions.

The number of experiments is small and the most appropriate control tissue (breast) has not so far been used, but the results in over 100 cultures in sera from two rats and two rabbits have been constant and positive. No instance was seen in which the antigenic tumour cells survived. In ten cases a few cells migrated out, but these succumbed after re-feeding with the antiserum. In the symbiotic antiserum culture heart muscle grew normally and beat for two or three days, in one case for six days. Kidney and spleen survived but grew somewhat less vigorously than in normal rat serum. In all the controls both cancer and normal tissue survived and grew well.

If the above experiments can, as I anticipate, be repeated consistently, the conclusion seems justified that antibodies more or less specific to cancer can be produced by its repeated inoculation into an animal of another species. Apart from this serum, all other agencies I have tried (heat, cold, radium, ultra-violet rays, bacterial infection) cause the death of normal tissues *in vitro* before that of cancer cells. On account of the dilution involved, and probably for other reasons, results comparable with those referred to above are not likely to be readily obtained *in vivo*, if, indeed, they can on these lines be obtained at all.

Further experiments *in vitro* and *in vivo* are in prospect both with animal and human cancer.

I am indebted to Prof. C. J. Martin, F.R.S., director of the Lister Institute, for putting a laboratory there at my disposal while carrying out the above research.

NOTES ON AN UNUSUAL CASE OF DIABETIC COMA.

By G. J. LANGLEY, M.D., M.R.C.P. LOND.,

PHYSICIAN, ANCOATS HOSPITAL; HONORARY ASSISTANT LECTURER
IN EXPERIMENTAL PHYSIOLOGY, UNIVERSITY OF MANCHESTER.

A SUFFICIENT number of records now exist to render the life-sparing effect of insulin in diabetic coma an established fact. The following record is made on account of the large amount of insulin required and the length of time that elapsed before consciousness returned.

History of Case.

A married woman, aged 35, was treated in June, 1923, for severe diabetes of nine years' duration. On discharge from supervision a diet was being taken containing 1850 calories made up of proteïn 120 g., fat 110 g., and carbohydrate 110 g., with two daily doses of insulin each of 25 units. The diet was so arranged that a large meal was given at 9 A.M. and again at 5 P.M., with two small meals containing very little carbohydrate at 1 P.M. and 9 P.M. In this way two daily doses of insulin sufficed. This arrangement maintained good health, fair exercise tolerance, and no great gain in weight, but permitted fairly frequent glycosuria. During August and September, 1924, large quantities of acetone appeared in the urine, but for this no medical advice was sought. The patient had been taught to use the nitroprusside test.

On the morning of Sept. 29th, 1924, the patient awakened to find that breathing was difficult and occasioned great pain in the right lower chest and right shoulder. An intense degree of air-hunger was later established which led to coma by 5 P.M. The urine was loaded with sugar and acetone, the blood-sugar was 0.4 per cent., and the patient was given glucose, 50 g., and 40 units of insulin.

The following notes give a very brief indication of subsequent events with blood-sugar readings at fairly frequent intervals. It will be seen that consciousness was not fully regained until midday of Oct. 5th, after the administration of 1100 units of insulin, and that contemporaneously the acetone became reduced to a mere trace.

Sept. 29th, first day: 9 A.M., very short of breath, pain under right lower ribs and in right shoulder. 12 noon, severe pain all over chest; given inj. morph. hypod., gr. $\frac{1}{4}$. Still short of breath. 4 P.M., typical air-hunger; conscious, but very ill and in great pain. Blood-sugar (b.s.), 0.4 per cent.; given 50 g. glucose and 40 units of insulin and removed from home. 7, b.s. 0.52 per cent., comatose, 20 units of insulin. 10.30, b.s. 0.52 per cent. 12 midnight, 40 units insulin.

Second day: 3.40 A.M., b.s. 0.52 per cent., 40 units insulin. 6.30, b.s. 0.52 per cent., 20 units insulin. 9, b.s. 0.52 per cent., insulin 40 units, air-hunger distinctly less. 12 noon, b.s. 0.52 per cent., 40 units insulin and 25 g. of glucose given. 3 P.M., b.s. 0.52 per cent., 40 units of insulin. 6, b.s. 0.52 per cent., 20 units of insulin and 25 g. of glucose given. 8, b.s. 0.52 per cent., 60 units insulin. 10.45, b.s. 0.52 per cent. In 24 hours passed 44 oz. urine, containing much sugar and acetone. Food consisted of weak bovril, brandy, and soda-water, vomiting occurred three times, coma was unchanged, but the air-hunger was much diminished. Volume of ingested fluid unknown.

During the third day the blood-sugar varied from 0.27 to 0.45 per cent., and 190 units insulin were given in seven doses. Urine in the 24 hours amounted to only 18 oz., containing much sugar and acetone with a trace of albumin. Vomiting occurred in small quantity ten times, and hiccough was present from time to time. Food consisted of weak bovril, chicken broth, brandy, one egg, and much soda-water. The air-hunger disappeared, but the coma remained unchanged.

During the fourth day the blood-sugar varied between 0.31 and 0.52 per cent.; 120 units insulin were given in six doses. Food as on previous day till 1 P.M., when it was limited to one part milk and two parts soda-water, given freely. Coma rather deeper. Urinary output only 10 oz., containing trace of albumin, with sugar and acetone still in large quantity. There was no vomiting, but the patient was extremely restless.

Fifth day: 2 A.M., b.s. 0.48 per cent., insulin 60 units. 5.30, b.s. 0.28 per cent., insulin 40 units. 7.45, b.s. 0.15 per cent., insulin 12 units. 12 noon, b.s. 0.12 per cent., insulin 12 units. 1 P.M., b.s. 0.09 per cent., slight sweating. 5.30, b.s. 0.16 per cent. 9.30, b.s. 0.26 per cent., insulin 10 units. The patient was incontinent the whole day and very restless during the first half, although much quieter later. The diet consisted of one part milk and two parts soda-water, taken freely. No return of consciousness accompanied the fall in blood-sugar; in fact, the patient seemed a good deal worse, and the pulse flagged in volume somewhat.

During the sixth day the blood-sugar varied from 0.44 to 0.48 per cent., and 215 units insulin were given in eight doses. Incontinence disappeared early in the day, the volume of urine passed was 93 oz., sugar being present but acetone much reduced. The patient was much less restless and only vomited once. Consciousness was partly re-established during the latter half of the day, and a fair response to simple questions was obtained.

During the seventh day the blood-sugar ranged between 0.16 and 0.36 per cent., and 150 units of insulin were given in seven doses. She became fully conscious at 10.15 A.M. Up till now 1170 units of insulin had been given. Urine passed 58 oz., containing sugar and some acetone. Vomiting only occurred once.

Discussion.

Several points of interest arise from this clinical record. In several previous cases glucose had been given, in spite of a high blood-sugar, because it had been suggested that insulin did not act as well against sugar derived from protein, and possibly from fat, as it did against glucose directly given,¹ and that therefore delay occurred in the removal of the ketosis. The subsequent findings in this case would go far to negative such a view, since no carbohydrate was given during the last four days of the coma. And further, Nash has shown that injection of insulin into phloridzinised dogs reduced the blood-sugar to the level of hypoglycæmic coma, the sugar in such dogs coming from the high protein wastage known to exist.²

The most striking fact is perhaps the very long delay in the recovery from coma. The air-hunger was materially reduced in severity after 12 hours of treatment, but persisted in easily recognisable form for 36 hours. After its disappearance coma still remained and showed no signs of reduction in degree. Sodium

bicarbonate was given by mouth throughout, but never in any larger dose than a drachm at a time. It is suggested that a factor which was overlooked in the treatment is possibly a very potent one—namely, the available phosphates.

J. B. S. Haldane has shown³ that acidosis may be induced by giving large doses of ammonium chloride by mouth, and that the acidosis so produced may be prevented or relieved by the administration of neutral sodium phosphate, which enables the kidney to secrete much more acid.

It is possible that had phosphates been given freely, a much more rapid recovery of consciousness would have taken place. Some support to such a view is given by the fact that after recovery the tongue remained for several days thickly coated with a brown fur, which did not clean in spite of much bicarbonate and constant buccal toilette; it, however, cleaned completely in 24 hours on the addition of 15-gr. doses of sodium phosphate to the diet. The fall of the blood-sugar to below the level of 0.1 per cent. might also be explained on this basis, for recovery of consciousness did not then take place.

The great reduction in urinary output on the third and fourth days in spite of a reasonable fluid intake and no marked sweating or diarrhoea is also difficult to explain. It certainly was not due to circulatory failure, for the heart throughout the attack gave no cause for great anxiety and the pulse remained of good volume and tension. During the period of limited urinary output a faint trace of albumin was found, but this disappeared immediately the secretion rose in volume and has not been found since. The bearing of diminished urine upon the blood-sugar must not be overlooked, for it follows that the sugar wasted by passage through the kidneys will not require the artificial aid of insulin for its combustion, and hence that if the sugar secretion via the kidneys is reduced a larger amount of insulin will be needed, it being known that insulin is capable of burning somewhere between one and two grammes of sugar per unit.⁴

The giving of food during coma is always a difficult problem. In this case the nutritive value of the food given was extremely low, but recovery took place when half a pint of milk was given every four hours and the insulin pressed until the blood-sugar was reduced to within normal limits. This would suggest that insulin acts best when the relative proportion of proteins, fats, and carbohydrates approaches most nearly to the normal, for it is surely tenable that milk would most likely represent such a combination.

There would seem to be little doubt but that sugar was produced in very large quantity from protein during the several days when no carbohydrate whatever was given, and during which the blood-sugar maintained its high level in spite of large and frequent insulin doses. And it would further seem that the administration of a properly constituted diet with the insulin allowed the vicious metabolic circle to be broken.

It is remarkable that although coma developed to the degree of incontinence, yet throughout the patient took fluids freely and easily.

Conclusions.

The conclusions submitted for consideration in this case are as follows: (1) That the failure of insulin to maintain good health in a diabetic patient is to be attributed to bad management and not to any ineffectiveness of the drug; (2) that recovery from prolonged coma is still possible by somewhat heroic dosage with insulin; (3) that insufficient treatment may keep the patient alive without overcoming the acidosis sufficiently to allow of consciousness being regained; (4) that a probable factor in delayed return to consciousness in some cases is the amount of available phosphate; (5) that insulin is effective alike against glucose administered and the sugar produced by protein breakdown.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

NON-SPECIFIC DISTURBANCES OF HEALTH DUE TO VITAMIN DEFICIENCY.

ON Feb. 16th this Society held a general debate on this subject. The chair was occupied by Sir STCLAIR THOMSON, the President.

Dr. LEONARD WILLIAMS, in opening the discussion, pleaded for an extension of the meaning of the word "vitamin" far beyond the limits of the three accessory food factors to which it was usually applied, for it was impossible to place a vitamin in a watertight compartment, and its fellows must be sought outside the orthodox trinity of fat-soluble A, water-soluble B, and anti-scorbutic C.

Supplementary Substances.

The first of the supplementary substances, he said, were the mineral salts. Dr. J. Boyd Orr had pointed out that the mineral might be present in a combination from which it could not be easily dissociated in the alimentary canal. Therefore the diet might suffice in amount, but owing to difficulty of assimilation, only a small proportion might be utilised. Orr showed that in the case of most minerals, both absorption from the intestine and excretion by the kidney were influenced by the amounts of other minerals present. Excess of magnesium had been shown by Hart and Steenbock to interfere with the utilisation of calcium, while phosphorus and calcium were mutually dependent on each other for utilisation; as also were calcium and iron.

Dr. Williams asked where the balance was to be obtained, except in Nature's laboratory. There were also the catalysts, which effected chemical changes without themselves taking part in those changes or being altered by them. Bayliss's work seemed to show that catalysts as found in Nature were essential to the proper utilisation not only of the mineral salts, but also of the proteins, fats, and carbohydrates. And in this category it was necessary to include the enzymes, which Bayliss defined as catalysts produced by living organisms. The enzymes were produced by friendly bacteria. The great influence of chlorophyll must also be taken into account, upon which all life depended, and which was manufactured by the vegetable kingdom alone. Speaking of the value of sunshine, he referred to the statement of Prof. Arthur Thomson that if rats kept on a deficient diet and not fortified by ultra-violet light were fed with the flesh of other rats which had been treated with ultra-violet rays, they thrived and escaped rickets. Moreover, Steenbock and Black had shown that if a food ration known to be deficient in rickets-preventing vitamin was exposed to ultra-violet light before being fed to the rats, it became adequate and sufficient. Turning to electricity, he said mineral salts were electrolytes; colloids had an electrical discharge, and enzymes were colloids.

It was important, he said, to recognise that each of the substances or agencies mentioned—mineral salts, catalysts, enzymes, chlorophyll, violet rays, and electricity—was either destroyed by heat or so altered as no longer to be recognisable as Nature's product, and so ceased to operate as our reinforcements, and might even become our enemies. He therefore declared that all disease, whether microbic or metabolic, was a function of cookery and concentration, and he urged the essential representation in food of raw fruits and raw vegetables.

Disturbances of the Gastro-intestinal Tract.

Lieut.-Col. R. MCCARRISON dealt with the subject of the disturbances on the gastro-intestinal tract due to vitamin deficiency. These disorders included

irregular action of the bowels, infection of the tract, chronic digestive disturbances with impaired absorption and assimilation of food, gastro-intestinal stasis, mucous disease in children, and colitis in adults. Vitamin deficiency of lesser degree continued for long periods might cause effects similar to those of greater degrees of this deficiency for a shorter time. There was found to be a great variation in individual idiosyncrasy among animals of the same species and age to chronic vitamin starvation, and in the animals used for experimentation on this subject there was a variation of results according to the pathogenic flora of their intestines. In general, these animal experiments were fairly applicable to man. The effects of vitamin deficiency were enhanced by want of balance of the food in respect to starch, fats, suitable protein or mineral elements, and he had used largely in his investigations wild monkeys which had been living their natural life in the Madras jungles. He related the careful experiments he had conducted, and said that the first effect of food deficient in vitamins was to render the intestinal tract—especially certain parts of it—susceptible to invasion by bacterial or protozoal agents. In due time the monkeys died, or were killed when about to die, and he found the following gross anatomical lesions: (1) enlargement of the mesenteric glands; (2) dilatation of the stomach; (3) congestion of the gastro-intestinal tract, with ecchymoses scattered over its peritoneal surface, most commonly in the colon; (4) ballooning of various parts of the tract; (5) marked thinning of the muscular walls of the colon, and partial disappearance of its longitudinal muscular bands. Various pathological changes were noted on opening the tract, including congestion and ecchymoses of the stomach, especially round the pylorus, shallow ulcers, papillary downgrowths of epithelium suggestive of commencing carcinoma in the pyloric region. In the colon there were varying degrees of colitis, sometimes involving the whole viscus. Colitis was the most marked and one of the most constant of the morbid anatomical changes present. He also found a number of histological changes in the tract, such as congestion and hemorrhage, atrophy of the muscular coats of the bowel, degenerative changes in the plexus of Auerbach, atrophic, necrotic, and inflammatory changes in the mucous membrane of the entire tract, but especially in the colon, bacterial invasion of the bowel walls, opening of portals of entry for bacteria into the blood-stream, and pronounced atrophy of the lymphoid elements of the intestinal mucosa. Rarely were all these changes present in all the deficiently fed animals, but most of them were. Usually they were more pronounced in the animals whose deficiency was in both A- and B-vitamins. Dr. Cramer had found that the digestion of fats was less complete and rapid in the absence of vitamins from the food, and that the vitamins, especially B, had a definitely stimulant action on the processes of intestinal digestion and absorption. Dr. Gross, using synthetic diets deficient in vitamin B, had shown, in vivo and in vitro, that it resulted in definite impairment of the motor functions of the intestinal tract; and Pappenheimer and Larimore showed that gastric lesions occurred in 55 per cent. of rats fed on synthetic diets in which the only deficiency was vitamin A. And they found that the addition of cod-liver oil afforded complete protection against those gastric lesions. Those authors commented on the fact that the gastric lesions resulting in their rats from food deficiency bore a remarkably close resemblance to those described by Fibiger as resulting from infestation by the nematode *Spiroptera neoplastica* which was present in their rats. The only reference to the diet of Fibiger's rats was the statement that they were fed solely on white bread. Col. McCarrison said he had noted in pigeons fed on a vitamin-deficient diet a tendency to favour the action of an invisible virus capable of causing epithelial new growth and of the disease known as epithelioma contagiosum. There was, Pappenheimer and Larimore pointed out,

a similarity of the hyperplasia produced by this virus to the papillary outgrowths and downgrowths of epithelium figured in some of their gastric lesions in rats; this was comparable to the downgrowths of epithelium, resembling commencing carcinomatous change, encountered in one of the speaker's monkeys which he experimented upon.

Col. McCarrison showed on the screen some very instructive slides to demonstrate the various lesions produced by the vitamin deficient foods which he had described.

New Specific Impairments in Health from this Cause.

Dr. W. CRAMER paid a tribute to the pioneer work of Col. R. McCarrison on the aspect of the vitamin problem under discussion. He was in agreement with most of Col. McCarrison's conclusions. Minor differences in their observations could be attributed to the fact that the speaker had worked mainly with single vitamin deficiencies operating on a synthetic diet with properly balanced inorganic salts, while Col. McCarrison had observed the effects of the deficiency of more than one vitamin in natural diets where other factors such as proteins of low biological value and a disproportion of inorganic salts were additional factors. Dr. Cramer protested against the extension of the vitamin conception as unjustified; he pleaded for a restriction of the term vitamin to the three food accessory factors, A, B, and C. Contrary to what had been stated light could not replace any of the vitamins. Several observers, including the speaker, had succeeded in rearing animals in the absence of light, but nobody had as yet been able to rear animals in the absence of vitamins no matter how much light was applied. All that light could do in those circumstances was to delay slightly the fatal issue.

Dr. Cramer pointed out that there was no justification for any fundamental distinction between specific and non-specific impairments of health due to vitamin deficiencies, as both were manifestations of specific pathological changes. The so-called specific deficiency diseases were merely the last links in the chain of events of which, he said, the non-specific impairments were the earlier ones. When vitamins were withheld from the diet, the health of the organism at once declined. There was loss of appetite, constipation, a gradual fall in the body temperature, a diminished nitrogen retention, an impaired absorption of food, and a progressive atrophy of the lymphoid tissue; and all those disturbances were specifically remedied by the administration of vitamin B. The latter vitamin, therefore, had a drug-like specific, stimulating action on the functions of the digestive tract, and he contended that a complete analogy existed between its action and the action of the hormones. In the case of both these substances the absence of the specific stimulus led to atrophic changes. Dr. Cramer said that a striking feature of mammals suffering from vitamin-B deficiency, even in its most advanced stages, was the absence of spontaneous infections, in spite of the condition in the animal of complete marasmus. He drew a particular distinction between the resistance of the organism to spontaneous infections and the resistance to experimental infections produced by injections of bacteria under the skin. The latter was said to be diminished in the case of the animal being fed on food deficient in vitamin B.

Vitamin-A Deficiency.

Animals suffering from vitamin-A deficiency presented the precise reverse condition, for they always developed spontaneous infections. These infections were observed to commence in the mucous membranes of the intestinal and the respiratory tracts, and in that of the eye. They were due to the weakening of the local defences of these tissues, represented by the mucus and the tears. But the general humoral defences of these animals remained unimpaired until long after the local infections were

established. The same diminished resistance to local infections had been observed in children, in whom xerophthalmia was always accompanied—sometimes preceded—by an infection, usually of the lungs. Therefore when in badly nourished children general infections occurred—e.g. pneumonia or enteritis—they must be regarded as specific deficiency diseases just as much as was the xerophthalmia. Dr. Cramer reminded the meeting of the condition of "vitamin under-feeding" to which he drew attention in 1922, in cases in which the intake of vitamins, though sufficient to enable the animals to grow and reproduce themselves, was not productive of full health. He also referred to the harmful effect of vitamin under-feeding in pregnancy, both to the mother and her offspring during lactation. Webster made an experiment in the vitamin under-feeding of mice, in which an intestinal infection with mouse typhoid was increased from a mortality of 20 per cent. to one of 100 per cent. It had been widely asserted, he said, that a civilised community living on a freely-chosen mixed diet was in no danger of suffering from a deficient vitamin intake, but Denmark furnished a refutation of this idea, as shown by the work of Blegvad and Widmark. Owing to economic conditions, the people of Denmark had suffered from an extensive vitamin deficiency, as indicated by the decreasing consumption of milk fat, and the increasing consumption of margarine. Similar conditions existed in this country, for the poorer classes, owing to their consumption of margarine, which was free of vitamin A, and their consumption of white bread, which did not contain vitamin B, were cut off from the main natural supplies of vitamins. It was not recognised that this steady deprivation resulted in a lowered standard of health, and the failure to recognise the importance of the matter was added to by the statement of leading authorities that the supply of vitamins was sure to be adequate if there were no specific deficiency diseases. The organism, especially in its young stage, required for its full functional development an abundant supply of vitamins, and restrictions of this intake would assuredly result in manifold disturbances of function.

Bone-marrow Changes.

Dr. G. M. FINDLAY spoke specially of the bone-marrow changes found in association with vitamin-deficient feeding. He said that the most important of the non-specific disturbances of health due to this deficiency was the increased liability to bacterial infection. In studying the reasons for this breakdown in the defence mechanisms, it was essential to investigate the condition of the leucoblastic tissues, especially those concerned with the formation of polymorphonuclear leucocytes. In animals fed on synthetic diets deficient in vitamin A, it was, he said, rare to find lesions in the leucoblastic bone-marrow, though in a very few adult animals which were maintained for many months on a diet deficient in vitamin A, an aplastic condition of the bone-marrow was observed. Associated with this was the fact that there was no reduction in the number of leucocytes in the blood-stream in this form of deficiency. In fact, after the onset of keratomalacia it was not uncommon to meet with a polymorphonuclear leucocytosis, and there was, at the same time, a fall in the bactericidal power of the blood, and this diminution of the function was present in all acute infections. Thus the infections associated with a deficiency of vitamin A in the diet were solely due to a local breakdown at the sites of infection, e.g., the conjunctiva, and the lining of the respiratory and intestinal tracts. Fleming had found, in the secretion of tears and of the respiratory mucous membrane, a substance—lysozyme—possessing a strongly lytic action on certain bacteria, and in rabbits with keratomalacia as a result of vitamin-A deficiency the lysozyme in the tears was greatly reduced. Indeed, in rats it was possible to prevent the onset of keratomalacia by washing the conjunctival sac with undiluted tears. Animals fed on diets wholly deficient in vitamin B showed numerous

small hæmorrhages in the bone-marrow. When vitamin B was not entirely withheld there was gelatinous degeneration in the bone-marrow, the leucoblastic cells being reduced in number. While the opsonic power of the blood and the ability to form agglutinins, hæmolysins, bacteriolysins, immune body, and antitoxin remained unimpaired, it was usual to find a fall in the bactericidal power of the blood of animals fed on diets deficient in vitamin B, and this seemed to be correlated with the synchronous fall in body temperature. Animals with lowered temperature lost their capacity to resist bacterial infections. Referring to deficiency of vitamin C, Dr. Findlay said that guinea-pigs with acute scurvy showed many small hæmorrhages in the bone-marrow. In chronic scurvy in that animal, which did not show definite clinical symptoms, the bone-marrow underwent either a gelatinous degeneration or a fibrotic change, one not confined to the epiphyseal ends of the bones. In conclusion, Dr. Findlay said the increased susceptibility to infection occurring as a result of these vitamin deficiencies did not apply to all bacteria, as diets lacking in vitamin did not modify the course of experimental tuberculosis in either guinea-pigs or rabbits.

The discussion was adjourned.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY.

A MEETING of this Subsection was held on Feb. 11th, Mr. F. SWINFORD EDWARDS, President, being in the chair.

The President opened a discussion on

FISTULÆ.

The subject he described as a specialty within a specialty. He referred to the paper he published in THE LANCET in 1918 (i., 673) and stated that he had nothing to add to, or retract from, what he had said then. Speaking of the genesis of the "horseshoe" fistula, which he believed to be much more frequently found than was generally supposed, Mr. Edwards said that the first step was the formation of an abscess in the mid-line dorsally between the two sphincters, due probably to an abrasion of the mucous membrane. Thence the suppurative process tracked above the ano-coccygeal ligament and the coccygeal fibres of the sphincter, which prevented the pus from coming to the surface in the mid-line and directed it to one or both sides, producing a semi or complete horseshoe fistula. The failure of operative interference he ascribed to (1) lack of a thorough acquaintance with the topography of the case and resulting incomplete opening out of the whole tract; (2) recurrence due to caries of the coccyx or tuber ischii, or the presence of a foreign body in the sinus; (3) infection with tuberculosis, though in his experience cases in which tuberculous caries was present healed very well, only two instances of callous wounds having occurred; he recommended the avoidance of operation when active tuberculosis was present in the lung, but the immediate opening of abscess cavities though less freely than in non-tuberculous cases; (4) the omission to remove overhanging margins of skin and mucous membrane; (5) injudicious after-treatment, painful or too abundant dressing, or too long confinement to bed. He stated that where the external opening lay behind a transverse line across the centre-point of the anal orifice the internal opening would be found as a depression between the two sphincters dorsally if the external orifice lay anterior to the mid-line the internal would usually (though not always) be found opposite. An anterior horseshoe fistula was unknown; where there were two or more external orifices in the perineum and the internal orifice lay to one side of the mid-line a branched fistula would be found. Mr. Edwards spoke of the danger of dividing the fibres of the external sphincter obliquely, healing being much more difficult in this case, and reminded operators

of the possibility of a deep sinus, running up at right angles to open into the bowel by a second internal orifice, joining the main fistula below in the mid-line dorsally. If such an extension were present the lower internal orifice might be felt between the sphincters as a depression; the upper as a small papilla. The high sinus should be laid open if its course was wholly submucous, but if such a treatment would involve cutting the internal sphincter it must be opened by a posterior incision from the lower part, producing a wide funnel-shaped cavity which was then freely curetted and packed. The application of silver nitrate solution or the solid cautery about a week later would generally give satisfactory results. In extensive cases the operation should be done in two parts, the first laying open all the side-tracts into the main posterior one, and the second, three to five weeks later, dividing the main dorsal sinus and the external sphincter. This was then a relatively small matter and usually resulted in a cure in two or three weeks more. The keystone of the operation for horseshoe fistula was the antero-posterior dorsal incision.

Discussion.

Sir C. GORDON-WATSON agreed as to the misleading impression usually conveyed by text-books in the matter of tuberculous fistulæ. Such cases were by no means hopeless. Many fistulæ might be tuberculous without the patient being tuberculous. In the latter case the fistula would do badly, but not in the former. Tuberculosis was no bar to a cure if the surgery and the after-treatment were correct. Referring to the President's statement that anterior "horseshoe" fistulæ were unknown, he thought that this indicated a difference in nomenclature, as the "branched" fistulæ, approximating very closely sometimes to a horseshoe shape, were undoubtedly found anteriorly. The high second internal opening was usually that of a submucous tract only, but when not submucous the granulation was very slow. He had at times ventured to open them up into the bowel, and although incontinence had resulted it had not been permanent. He emphasised the importance of the two-stage operation, and ascribed failures to an incomplete opening up or else to an over-bold primary opening. He believed in the use of primary suture in suitable cases, and referred to a series of 17 cases he had shown before this Section, in which the results, combined with the use of flavine, bipp, or ether, had been excellent. Even if it failed, ground had not been lost, as granulation followed, and if it were successful the convalescence was much shortened. The results of using Finsen light to encourage the healing of very chronic cases had also been gratifying.

Mr. W. E. MILES said that the average surgeon did not realise that there were more types of fistula than one, and referred to the text-book classification, emphasising the point that the track of a fistula is an unobliterated abscess cavity, and that the four varieties distinguished should be the subcutaneous, the submucous, the ischio-rectal, and the horseshoe. The disposition of the fistula was entirely due to the process of dissemination by lymphatics. The difference of opinion as to whether the high internally-opening track could be opened with impunity was due only to a failure to differentiate between the track resulting from a submucous abscess and a pelvi-rectal one. What really mattered in the question of incontinence was the division of the point of convergence of levator ani with the sphincters. He urged the importance of making the surface area of the wound greater than the area of the two sides, otherwise the epithelial layer would be completed before the granulation from below had come up to meet it. Mr. Miles was in the habit of making three or four relief incisions at right angles to the opening incisions. He opposed the packing of the wound on the ground that this resulted in a surface depression, which, if it crossed the anal margin, resulted in a mechanical incontinence apart from any muscular damage.

Mr. ASLETT BALDWIN spoke of the value of ionisation, particularly for the case with high internal orifice. In one very severe case, where operation had been refused, the passage of a pure zinc electrode along a director, with ionisation on the track in pieces, had resulted in complete comfort for the patient. A callous surface, whether simple or tuberculous, could always be made to heal with zinc ionisation.

Mr. IVOR BACK suggested that the constant situation of the internal orifice between the two sphincters was due to a tearing of the anal papillæ by the passage of a constipated motion, producing a crack which subsequently became infected. He believed that the infection did not usually track diagonally across between the two sphincters, but that its common course was external to the external sphincter, producing an ischio-rectal abscess; the resulting fibrosis behind it would leave a mass of hard tissue which was what was cut by the surgeon when he believed he was cutting the external sphincter. In the cases where the fistula really seemed to lie between the two sphincters he suggested that it was the result of a long-standing process tracking round again from the ischio-rectal fossa. He classified fistulæ into (1) those with an internal opening; (2) those with a high internal opening, always secondary to one lying between the sphincters, and representing the upper pole of a submucous abscess working upwards—the treatment was to open up as for an ordinary fistula and then open the submucous tract into the rectum; (3) the pelvi-rectal abscess, which had nothing whatever to do with the rectum, but indicated tuberculosis of the viscera, ovary, or pelvic bones, and could not possibly be opened right up. He believed firmly in the value of primary suture, and considered that cases of failure of this method were due to the stitches not being put deep enough to include the whole cut area, but crossing the incision above its lowest part and so leaving an empty open space beneath the united portion. He spoke of the value of sunlight, artificial or real, in the healing of obstinate cases.

Mr. L. NOBBURY agreed with the previous speaker as to the relation of the fistula to the external sphincter, but thought that in some cases the fistula might track between the fibres of the muscle. He also agreed as to the operability of tuberculous cases, referring to several very bad cases on which he had recently operated under spinal anaesthesia with complete healing. He asked if any member had had experience of the development of malignant disease in fistulæ.

Sir C. GORDON-WATSON described a case of malignant disease occurring on the site of a non-healed horseshoe fistula, shown to the Proctological Society some years ago. The man had died some three years later with a large mass of secondary deposit in the liver.

Reply.

The PRESIDENT, replying, spoke further of the pelvi-rectal abscess which he regarded as very rare; all his cases had been the result of gonorrhœal prostatitis with peri-prostatic abscess. A high rectal carcinoma might have a pelvi-rectal abscess and fistula as a secondary result.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held at the University of Bristol on Feb. 11th. In the absence of the President, Mr. J. LACY FIRTH took the chair.

Mr. PERCY SARGENT read a paper on the

Surgery of Tumours of the Central Nervous System.

He laid emphasis first on the necessity for accurate diagnosis. Coöperation between the neurologist and the surgeon must be close, and the former must afford the earliest opportunity for the latter to give that help to the patient which, in these cases, operation alone could bring. He proposed to speak of four classes of tumour.

Tumours of the Pituitary Region manifested themselves in two ways. Function was disturbed, with changes in the skeleton, in other glandular functions, producing such conditions as hairlessness, and pressure produced intolerable headaches with failing vision. It was for the latter symptoms that, in the present state of our knowledge, the skill of the surgeon was sought. These tumours fell into two divisions. 1. Simple adenomata of the pars anterior excavated the sella, and also pushed up the optic chiasma, but in invading the cranial cavity they remained encapsuled. It was with these types of tumour that the glandular disturbances might occur; and one must bear in mind that such patients bore operations badly. 2. The other division was composed of suprapituitary tumours: (a) meningeal tumours of the interpeduncular space, (b) tumours or cysts of complex structure probably arising from the infundibulum. With these the glandular changes are not remarked. Either type may be approached (1) by the temporal route used by Horsley 20 years ago, (2) from below through the sphenoidal sinus as advocated by Cushing, (3) by means of a frontal osteo-plastic flap as devised by Frazier. The speaker preferred the last method. The prognosis was best with adenomata; with improvement in technique the proportion of satisfactory results was quite gratifying. Suprapituitary tumours were less satisfactory to deal with. Some were cystic, and contained cholesterol; with these there seemed to be a risk of death from toxæmia following the liberation of the fluid.

Cerebello-pontine Tumours were usually neuro-fibromata of the auditory nerve. Others were cholesteatomata, or "pearl tumours." The former were usually firm, solid, encapsuled tumours, but might be soft or even cystic. They enlarged the internal auditory meatus, sometimes to a remarkable degree; this could be demonstrated by skiagraphy. Deafness and tinnitus might be the only symptoms for years. Loss of function of the vestibular part of the nerve was early demonstrable. Loss of the corneal reflex of the same side was also frequent. Later, the classical signs of tumour, headache, vomiting, and papilloedema appeared. By this time operation had become a more difficult, as well as a more hazardous, procedure. The tumours should not be removed en masse; this could be done, but the resulting disturbance to the vascular supply of the medulla commonly induced death; the tumour should be removed intracapsularly by morcellement. This method had given the speaker a mortality of 3 only in 19 cases. Decompression might be done if piecemeal removal was not thought advisable, but the results were not nearly so satisfactory.

The group of *endotheliomata* was histological rather than regional, though the tumours were meningeal and tended to be superficial. They cupped but did not infiltrate the brain, and probably arose from the arachnoid tufts which formed the Pacchionian bodies and so tended to be found about the longitudinal sinus. Growing very slowly, they might attain very large size before giving rise to symptoms. These tumours might often be diagnosed and localised with certainty before signs of general pressure appeared. This was a great advantage as an osteo-plastic flap could be employed. A two-stage operation was not advised; the patient might die between the two operations. These tumours formed only a small proportion of the whole class of tumours of the cerebrum and were rare in the cerebellum. The glioma of an infiltrating type was the common tumour. For these, decompression and partial removal gave some relief, and it seemed that gliomata were tumours favourable for the action of radium buried in their substance. In any case, where there was a high degree of intracranial pressure, any operation was fraught with difficulty and danger; the classical signs of tumour should be regarded rather as danger signals or even portents of impending death. Early and accurate diagnosis were the points of essential importance.

Spinal Tumours, he said, provided some of the most gratifying results of operation on the central nervous system. A large proportion were benign extra-medullary growths, and in all these there must be some stage where operation afforded prospect of complete removal at very small risk. In addition to neurological means of diagnosis and lumbar puncture, skiagraphy after injection of lipiodol through the occipito-atlantoid ligament afforded valuable means of localising the tumour.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held recently, Dr. PETER HOWIE, the President, in the chair, when Dr. A. G. ANDERSON read a paper on

Encephalitis Lethargica.

Dr. Anderson's experience of the disease extended to some 20 cases, and he outlined the various points of interest which had emerged from the study of these cases. After describing the original appearance of encephalitis lethargica in 1917 and its spread in different countries, and stating that the description of "lethargic" was now inapplicable to many of the recent cases, Dr. Anderson recounted the details of the first case he had seen on March 17th, 1920, in a woman of 37, who presented the typical features of fever, ocular disturbance, and lethargy which lasted for seven or eight days. The most interesting feature was that in a few days the mask-like facies developed, and by the end of May the typically stiff gait like a case of paralysis agitans had appeared. During the next two or three years the residual phenomena noted were the mask-like face, the stiff hesitating movements of the limbs—the arms being held in the characteristic mid-brain attitude. Fortunately, the Parkinsonism was not progressive, and during the past year the patient had emigrated and was able to do active work. Dr. Anderson then discussed the development of the mid-brain syndrome, and indicated that this was now regarded as one of the commonest sequelæ of encephalitis lethargica, the time of its appearance being extremely variable.

In the description of further cases of the series Dr. Anderson dealt fully with the various characteristic symptoms and signs which had appeared, and discussed their features especially as regards period of onset and diagnostic and prognostic import. Such were Parkinsonism, lethargy, muscular and mental passivity, the running gait, akinesia paradoxa, disorders of speech, tremors, emaciation, excitomotor phenomena, pain, myoclonus, chorea, athetosis, spasmodic tics and automatic movements, facial paralysis, and signs simulating meningitis. One patient had a pregnancy after the onset of the encephalitis, a healthy child being born; the case illustrated the facts that encephalitis does not necessarily lead to premature labour, that the child need not be infected, and that pregnancy seems to have a definite effect in aggravating an existing Parkinsonian syndrome. In connexion with the choreic type of case Dr. Anderson described fully two cases: one, a boy of 14, who had attacks nightly lasting about four hours, when he went through a series of "antics"—coughing, snorting, jumping in and out of bed, and so on, till he fell asleep exhausted. The other case, also a boy of 14, had similar restless attacks with very marked insomnia, the wakefulness persisting till 4 or 5 A.M.; one period of insomnia lasted for 48 hours. This boy also had attacks of marked respiratory disturbance. The mental and moral changes in the disease were next discussed, and their problems indicated.

In conclusion, Dr. Anderson dealt with the theories of the infective nature of the disease, referring to cases which might lend clinical support to the idea. He also briefly referred to the necessity of a complete examination of the cerebro-spinal fluid in all cases, not so much for the possible positive findings as for

the information obtained making it possible to exclude other diseases. He stated that there was no really characteristic picture of the cerebro-spinal fluid in encephalitis lethargica except that it differed from most other diseases in that the sugar-content was invariably high. He pointed out also that in this disease the virus remained in the nervous system for long periods of time, waking into activity at intervals, and affecting different parts of the brain at different times; so that the original conception of a disease with an acute stage passing off and then followed by certain residual phenomena was no longer tenable. No form of treatment so far had been found to have the slightest effect, but in Dr. Anderson's opinion any form of effective treatment which might be discovered would probably be in the nature of an anti-serum rather than drugs.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

At a meeting of this Society held on Jan. 21st Mr. DAVID LEES showed a cinematograph film prepared by Colonel L. W. Harrison on the

Diagnosis and Treatment of Gonorrhœa in the Male.

The film in a graphic and diagrammatic manner showed the progress of infection of the genito-urinary tract, the spread of infection, and complications likely to occur both immediate and late, and also demonstrated the importance of a knowledge of the anatomy and histology of the urinary tract in diagnosis, treatment, and in tests of cure.

Exhibition of Clinical Cases.

Mr. Lees showed two clinical cases and described a third.

1. *Juvenile Paresis.*—This patient, a boy aged 12, was admitted to hospital with definite spasticity of the legs and could not walk. Definite evidence of congenital syphilis was obtained both from the family history and the appearance of the fœces. The case presented, in addition to the spasticity of the lower limbs, lowered intelligence, inequality of the pupils, and exaggeration of the reflexes with marked clonic contractions in both ankle and knee reflexes. Localisation of the lesion was difficult. The specific infection had not involved grossly one definite area and a diagnosis of meningitis and myelitis was all that could be arrived at. The multiplicity of symptoms indicated that the prognosis was likely to be poor, and this was confirmed on examination of the cerebro-spinal fluid, which showed a strong positive Wassermann, increase of cells and globulin, and the so-called parietic curve in the colloidal gold test. The interesting point in the case was the amount of salvarsan that had been tolerated; this boy had tolerated more than an average adult dosage with increase of weight and general improvement; the importance was emphasised of forcing the dosage in the early stages. Careful re-education by exercises was practised, together with massage and tonic treatment.

2. *Juvenile Tabes in Association with Systemic Syphilis.*—The patient, a boy aged 12, was admitted to hospital suffering from subacute osteo-myelitis of the tibia, which on X ray examination showed definite sclerosis of the bone. In view of the subacute nature of the condition arsenic and bismuth were given with a very rapid result in easing the pain and causing general improvement of the patient. The father of this patient was at present under treatment for tabes, and the boy showed a definite Argyll Robertson pupil; the case was treated with silber salvarsan and bismuth with great improvement. There was a great cellular decrease in the cerebro-spinal fluid, from which globulin, though previously markedly increased, was now absent. The Wassermann test was still definitely positive, but it was hoped that with further treatment this would be negative and that the later symptoms of the tabes would be prevented from appearing.

3. *Case for Diagnosis.*—This patient, a man aged 53, was admitted to hospital with a condition resembling a double Charcot's disease of the knee-joints. The history was that 20 years ago he contracted gonorrhœa, but no history of syphilis is given; he had multiple arthritis in the left knee 14 years ago, and in the right knee four years ago.

For the last two years the joints had been painless, but now showed a bilateral arthritis with irregularity of the joint surface clinically suggesting Charcot's disease. On examination no appearance of any lesion, either of the genitals, skin, or mucous membranes was found, there were no signs on examination of the eyes with the exception of early choroiditis; the pupils reacted to light and accommodation equally and well. Knee-jerks and ankle-jerks were present, likewise the abdominal and cremasteric reflexes; there was no disturbance of sensation and no ataxia or incoördination—in fact, not a single sign or symptom which would suggest that the patient was suffering from the disease. The Wassermann reaction in both blood and cerebro-spinal fluid was negative, in the cerebro-spinal fluid globulin was negative, the cell count was 1 per c.mm., the colloidal gold test 001332210000. There was no clinical evidence of gonorrhœa except an enlarged left vesicle; the prostatic and vesicular secretion contained pus cells in excess, but no organisms; the complement-fixation test for gonorrhœa was negative. X ray examination showed appearances resembling Charcot's disease; fluid aspirated from the joint showed no cellular deposit, and was sterile. The question was whether this condition was Charcot's disease, gonorrhœal arthritis, or osteo-arthritis.

Miss GERTRUDE HERZFELD described a case of an infant who developed ophthalmia neonatorum four days after birth; a fortnight after birth swellings appeared in the left carpo-metacarpal joint and the right elbow; this latter increased and six days later was aspirated, the fluid showing gonococci. Three and a half weeks after birth the elbow and hand were opened and pus removed from both joints. After this swellings appeared in the right ankle and left knee, an autogenous vaccine was given but without immediate effect, and both these joints were opened and pus evacuated. At present the joint swellings were subsiding, the first to be incised had healed, the others were still discharging to some extent. Vaccine was being injected with apparent benefit and without marked reaction.

Mr. J. M. GRAHAM showed a pathological specimen of *Charcot's Disease of the Hip-Joint.*

The specimen was from a woman aged 46, admitted to hospital as a case of sarcoma of the hip and who died unexpectedly a few days after. The patient had been known to suffer from tabes for four years, but when under treatment in a medical ward there was no evidence of any trophic change, and up to four months before admission she was able to walk well. Quite suddenly the right leg began to swell and she noticed shortening of the leg. Her doctor was called in and found a large tumour extending from the lower part of the iliac fossa down almost to the upper third of the thigh. On admission to hospital the condition was diagnosed as Charcot's disease, and this was confirmed by X rays. The specimen showed enormous increase in the area of attachment of the capsule which was markedly thickened, and with enormous thickening of the synovial membrane, the processes in great masses resembling a nail-brush. There were large definite tumour-like formations undergoing calcification. Sessile nodules were present but not loose bodies. The bone showed gross changes and the acetabulum was almost devoid of cartilage, and many large bursæ were situated around the joint.

ULSTER MEDICAL SOCIETY.

At a meeting of this Society on Feb. 5th, Dr. J. SINGLETON DARLING, the President, in the chair, Dr. A. GARDNER ROBB read a paper on

Epidemic Encephalitis in Belfast in 1924.

The outbreak in Belfast began at the end of March, 1924. For the first few weeks the cases were few; about the middle of April there was a sudden large increase of admissions to the Belfast fever hospitals, and the cases continued to come in in large numbers until the end of June, when the epidemic ceased even

more suddenly than it had begun, only one case occurring after that date. This seasonal outbreak coincided exactly with the experience in Belfast in the year 1920, the only other year in which there has been a serious epidemic. In that year the first cases were notified in March, there was a large increase in April, a still larger number in May, then a rapid fall in June, and by the middle of July the epidemic was at an end. The total number of cases admitted to the fever hospitals in the recent outbreak was 183, and 90 per cent. of these were admitted within two months—viz., from mid-April to mid-June. The prominent symptoms at the onset were: (1) Fleeting superficial neuralgic pains. (2) Nocturnal insomnia, often complete and lasting for several nights. (3) Mental excitement and exaltation, great restlessness, and talkativeness. A little later came: (4) Diplopia and other eye symptoms. (5) Muscular twitchings of varying degree. (6) Delirium of varying degree. (7) Lethargy of varying degree. In many cases one or more of these symptoms were absent. The neuralgic pains were usually on the scalp, over the ears and sides of the neck, down the arm, on the forearm and fingers, especially the thumb; over the iliac crests, unilateral at first, later bilateral. In some cases the pains were in the leg, foot, or axillæ. It was noticed that while light touching or stroking was intensely painful, firm handling caused little or no pain. Nocturnal insomnia was a very early symptom and sometimes lasted for several nights. Some patients were very excited and talkative, and in many cases the patient, if left alone, sang or whistled throughout the entire night. Diplopia was present in 73 per cent. of cases; usually it was not observed until the second or third day. Squint, ptosis, nystagmus, and partial loss of accommodation were frequent. Muscular twitchings were present in 70 per cent. of cases; they were mild or severe. In some cases they were as severe as in severe chorea. Myoclonic jerkings of the abdominal muscles were common. Delirium was noted in 52 per cent. of cases. It varied from a low muttering type to severe maniacal states. It usually quieted down after a day or two. Lethargy was present at some stage in 72 per cent. of cases. It appeared usually in the third or fourth week and varied in degree. In many cases it was at first present only in the daytime, the patient being wakeful at night. Later it was continuous, and in a few cases there was profound coma lasting for weeks. Herpes occurred in 6 per cent. of cases. Attacks of dyspnoea were frequent. Polyuria was common. Lumbar puncture was performed in many cases. Little that varied from the normal was found except an increased sugar content. This point is one of diagnostic value. Paralysis of the facial muscles was rare. In only a very few instances was there more than one case from the same house. No member of the staff at the hospitals contracted the disease. In the 183 cases admitted the mortality was 11·4 per cent. Pregnant women did not show a mortality above the average. Many cases recovered temporarily and returned to work, only to relapse later. Opinions differed as to the proportion of cases of complete recovery. Some physicians put the figure as high as 25 per cent. or even 50 per cent. Dr. Robb thought this figure much too high. He thought 5 per cent. was nearer the mark. In the vast majority of cases some residual effects persisted.

As regards treatment there was no drug of proved value. Hexamine did not seem to possess much influence. Salicylate of soda had little influence over the pains of the disease. Paraldehyde was the best hypnotic. The turpentine ("fixation abscess") treatment, the use of diphtheria antitoxin, the intravenous injection of the patient's own cerebro-spinal fluid, frequent lumbar puncture, intramuscular injections of sterilised milk, were methods which he could not recommend. Hyoscine was of some value in dealing with Parkinsonism. He agreed with Prof. Hall that "at present any reliable therapeutic, either for the disease itself, or for its many after-results, does not exist."

Reviews and Notices of Books.

EXAMINATION OF WATERS AND WATER-SUPPLIES.

Third edition. By JOHN C. THRESH, D.Sc., M.D., and JOHN F. BEALE, B.A., M.R.C.S. London: J. and A. Churchill. 1925. Pp. 590. 25s.

A THIRD edition of this standard work is welcome at a time when so many matters of moment in connexion with water-supply are in a state of flux. The book which is, in most respects, thoroughly up to date, is arranged in five parts, with 33 chapters, a useful appendix and admirable index, and between the two covers lie 590 pages.

Part I. deals with reasons for which waters and their sources are examined—geology in relation to sources of supply and the character of water which is derived from different geological sources. This is a particularly useful section wherein the authors lay great stress on the topographical observations. Part II. occupies 111 pages and deals adequately with many aspects of the question. The chapters on the examination of (a) the sources of surface water-supplies, (b) rivers and streams, (c) springs and wells, and (d) waterworks, reservoirs, and mains, make good reading. When recommending *B. prodigiosus* as a test organism for tracing pollutions, the authors are not quite correct in saying that this microbe is very rarely found in any water-supply. (Chapter VIII., on the purification of water by storage, is fragmentary and sometimes even a little misleading. The statement that "rivers and streams in flood . . . recover their pristine condition in two or three days" is too sweeping an assertion. The questions at issue are for how long under conditions of low temperature, ground saturated with water, and recurrent rainfall, do rivers yield results continuously bad, and what duration of storage should be aimed at in order to secure safety. The fact that chlorination is a short cut to purity is not evidence against the desirability of prolonged storage without chlorination in the interests of the water consumer. In the account (p. 106) of the 1906 chlorine experiments at Cambridge the names of Otto Hehner and Alexander Houston, who were associated in the inquiry with Sims Woodhead and Dr. Thresh, are not mentioned. It is stated on p. 116:—

"Hertford is probably the only town in England where chlorine is added to the sewage effluent, and this is because the effluent enters the River Lee not far above an intake of the Metropolitan Water Board. Now that chlorination is being carried out at the waterworks, the chlorination of the exceedingly dilute effluent from the Hertford works is probably unnecessary."

The river Lee has never been chlorinated and is alone affected by the discharge of the Hertford sewage effluent. The New River is chlorinated, but the intake is above the point of discharge of the Hertford sewage effluent.

Chapter XI., on the purification of water by means of lime, is welcome. Workers from all parts of the world have been to see the authors' experiments at the Langford station, and the results obtained have attracted great attention. If the advantages of the excess lime method ultimately become widely recognised, it will be largely due to Dr. Thresh's patient investigations and his tenacity of purpose. The description of the processes for the softening of water and removal of iron are useful, but possibly too brief. An important chapter deals with the treatment of water to prevent action on lead and to remove colour. If soluble silicates can achieve the remarkable results the authors have outlined, Dr. Thresh deserves cordial congratulations on the outcome of much careful work. The chapter on the suitability of water for swimming baths and for trade purposes will be welcomed by a wide range of readers.

The third part of the book is devoted to a bold and able attempt to clear up our somewhat hazy conceptions as to what constitutes a "pure and wholesome water." It is not easy to give a definition that will be recognised as universally applicable, but it is certain that with modern methods of purification it is, at all events, safe to use waters for domestic consumption which in the old days would have been undoubtedly rejected. The authors' conclusions as to the permissible limits of various salts in water will be generally accepted as reasonable. A chapter on the interpretation of the results of physical biological, chemical, and bacteriological examinations, is full of interest, though the section devoted to odour and taste is disappointing. A chapter on electro-conductivity and hydrogen-ion concentration is a most welcome addition. The interpretation of the results of bacteriological examination of waters is one of the most important in the book. The authors complain, with good reason, of the wording of some bacteriological reports, which often create quite unnecessary alarm. It is wrong to say of a water going perhaps to a million or more consumers that it is "quite unfit to drink," or "dangerously polluted" simply because it contains *B. coli*, when the water has been drunk for years with perfect safety. Bacteriologists should, of course, aim at a high standard of purity, but a chance sample of water containing *B. coli* in 100 or even in 10 c.cm. does not necessarily indicate an alarming state of affairs. It is one thing to say that a sample does not reach the highest standard of bacteriological purity and quite another thing to assert that it is actually dangerous to health. The authors show wisdom in the following caution:—

"Too great an importance must not, however, be attached to bacteriological results, since great care is required in their interpretation. Want of experience, or a too rigid adherence to empirical standards, may easily lead to erroneous conclusions. Some knowledge of the history of a water is in most cases absolutely necessary in order to enable correct inferences to be drawn."

The book is comprehensive, and other sections deal with the interpretation of chemical analyses, analyses for sanitary and other purposes, collection of samples, physical examination, character of suspended matters, chemical analysis, examination of grossly polluted waters, softening of water and excess lime process, action of water on lead, estimation of saline constituents, and special analyses, a table of analyses of waters from various geological sources being provided.

A certain intolerance of opposing views is noticeable on occasion throughout the book and the significance of the experiments carried out by other observers is not always correctly interpreted, but the volume as a whole has great merit as a practical contribution to the literature of water-supply.

PNEUMONIA.

Its Pathology, Diagnosis, Prognosis, and Treatment. By the late R. MURRAY LESLIE, M.A., B.Sc., M.D. Edited and revised by J. BROWNING ALEXANDER, M.D., M.R.C.P. Lond. London: William Heinemann (Medical Books), Ltd. 1924. Pp. 351. 12s. 6d.

THIS book was commenced by Dr. Murray Leslie in 1919, and had practically reached completion when the author died. Dr. Browning Alexander has revised the work and brought the bacteriological section up to date, as well as the sections dealing with vaccine therapy. The book is a comprehensive survey of the epidemiology, ætiology of pneumonia, and of the clinical practice in its treatment. Practically all the ground relating to this ubiquitous disease is well covered.

A fairly full account is given of the researches at the Rockefeller Institute on pneumococcus types, but there is a regrettable tendency to use the words "type" and "group" as though they were synony-

mous terms. Serum therapy, including both the old antipneumococcal sera and the new serum of the Rockefeller Institute, receives due attention. Vaccine therapy is dealt with in a final chapter, where the opinion is expressed that there is little appreciable difference in the course of the disease when untreated or treated by vaccines. On the clinical side the use of alcohol (1) as a food, (2) as a drug is discussed at length. The administration of oxygen is dealt with in detail, and the various methods of using oxygen described. The thorny subject of digitalis therapy is well discussed.

In the chapter on diagnosis a short section has been devoted to radiographic diagnosis which is perhaps more commonly used abroad than in this country in cases of pneumonia. The authors consider that this relatively new method of diagnosis has thrown considerable doubt on the hitherto accepted ideas regarding the so-called central pneumonia. The chapter on prognosis is one of the most interesting, especially when read in conjunction with the later section on the maintenance of the circulation. The authors rightly lay stress upon the cardio-vascular system in this connexion, and suggest as a working maxim, "Take care of the heart, the lungs will take care of themselves," though they point out they do not wish to imply the early and continuous use of cardiac stimulants.

The book should find a ready public, since it is written from a common-sense point of view by two clinicians who have a wide experience of the disease, and who will be recognised as a sound guide by practitioners.

CLINICAL ASPECTS OF THE ELECTROCARDIOGRAM.

By HAROLD E. B. PARDEE, M.D., Associate in Medicine, Cornell University Medical School; Consulting Cardiologist, Lying-in Hospital and Woman's Hospital, New York City. New York: Paul B. Hoeber, Inc. Pp. 222. 1924. \$4.

THE author of this well-written book has given the reader all that he can be expected to know about clinical electrocardiography. In this volume nothing of clinical importance likely to assist in the interpretation of the electrocardiogram has been omitted, nor has any neglect been shown in dealing with the experimental evidence upon which our knowledge of this subject, in the main, depends. It is a work which can be recommended to all who intend to specialise in disease of the cardio-vascular system and to the cardiologist who already has a working knowledge of the electrocardiograph.

It is not a book for the general practitioner. He should not be expected to be familiar with all the current knowledge of clinical electrocardiography, nor the experimental observations and theories upon which the interpretation of the electrocardiogram is based. There are ten chapters, all of which are well illustrated with helpful diagrams and electrocardiographic records which are exceedingly well reproduced. The subject-matter is dealt with in a clear, concise style under such headings as Disturbances in Rate and Rhythm, Clinical Aspects of Disturbances in Rate and Rhythm, the Use of the Electrocardiograph in the Examination of Patients.

The author at all times endeavours to keep the clinical aspects of his subject in the foreground, and refers to experimental observations only when they are likely to afford information of clinical importance. In discussing premature beats, he distinguishes those which are of no prognostic importance and others which indicate structural disease. This distinction is not based on experimental evidence, nor are clinical observations recorded which support the view that premature beats as an isolated sign are of prognostic importance. It is realised, for obvious reasons, that electrocardiographic records cannot be obtained in all patients; it is important, therefore, that this method of examination should not be omitted when an electro-

cardiogram is likely to give information of diagnostic and prognostic value. The type of patient who may have an abnormal electrocardiogram is described, and the significance which one should attach to electric curves in these clinical groups is discussed. Einthoven's tables for the determination of the direction of the heart current recorded by the three standard leads are given in an appendix. The bibliography is conveniently arranged under subject-headings.

THE CHEMISTRY OF ENZYME ACTIONS.

Second and revised edition. By K. GEORGE FALK. New York: Chemical Catalogue Co. 1924. Pp. 249.

In this small volume the author has attempted to provide a summary of modern views and theories with regard to enzyme action. After an interesting introduction Mr. Falk considers in detail the factors affecting enzyme reactions, notably the velocity, temperature, and colloidal influences. Among the most interesting chapters are those dealing respectively with the mechanism and the use and application of enzyme action. A chapter upon enzyme actions and tissues and tumours is included. The volume contains little original matter, but it presents an excellent summary of current views. Full references are given and the descriptions are clear and accurate.

PRINCIPLES AND PRACTICE OF OBSTETRICS.

Fourth edition. By JOSEPH B. DE LEE, A.M., M.D., Professor of Obstetrics at the Northwestern University Medical School, Chicago. Thoroughly revised. London and Philadelphia: W. B. Saunders Company Ltd. 1924. With 1128 illustrations on 923 figures, 201 being in colours. Pp. 1123. 55s.

THE fourth edition of this very complete treatise on obstetrics has been thoroughly revised; many of the less satisfactory illustrations have been replaced. The author deplores excess of zeal in undertaking obstetric operations and maintains a strongly conservative attitude throughout the book. A watchful and armed expectancy, he says, has proved to give the best results. He strongly condemns the indiscriminate use of pituitrin as practised to-day; we agree that this drug should not be used until after the child has left the uterus. Antenatal care is fully discussed and emphasis is laid on the value of the proper conduct of the hygiene of pregnancy as a means of preventing complications. Dr. De Lee does not believe that eclampsia can always be prevented; in discussing the treatment of this disease he states that prompt delivery will save most mothers and children—that is, if the patient is in skilled hands; but if operative skill and experience are lacking, he is strongly in favour of the conservative treatment of Stroganoff preceded by a generous venesection. His objection to eliminative methods, especially colonic flushing and catharsis, is that they soil the field of operation. The section dealing with parturient injuries of the higher pelvic fascia and pelvic floor is very good, and several new illustrations have been added here. The author lays great stress on the proper repair of these injuries and is a strong advocate of episiotomy as a prophylactic measure. He considers that an important cause of perineal tears is a narrow pubic arch, and is convinced that a large number of the deep lacerations in forceps cases are due to the unrecognised funnel pelvis. With this observation we are in entire agreement, but apparently marked contraction of the outlet is more common in America than in this country.

Dr. De Lee is an enthusiast for the new transperitoneal cervical Casarean section, or laparo-trachelotomy as he terms it. He believes that this operation should replace the classic one in all but a few exceptional cases, as it can be performed after

a woman has had a real test of labour and in cases where the abdominal section would not be considered—e.g., after a few attempts with forceps have been made and even where there is a slight possibility of infection; he considers that this procedure should almost eliminate the necessity of craniotomy on the living child. He claims for laparo-trachelotomy the following advantages: that the incision is made in the lower uterine segment and consequently there is less hæmorrhage and shock, that the intestines are not disturbed, and the field is not soiled by the uterine contents. Post-operative complications are rarer, adhesions are reduced to a minimum, and there is less likelihood of subsequent rupture of the uterus, there being only three cases reported to date. The maternal mortality is less, and out of 266 cases operated upon at the Chicago Lying-in Hospital there has only been one death, although many of the cases were unfavourable ones. Twelve new illustrations of this operation with full descriptive legends have been added, and these give an excellent idea of the technique employed. Without sharing the author's optimism, we think he has made out a good case for transperitoneal cervical Casarean section, and we await the publication of a larger series of cases with interest.

This new edition fully confirms the favourable opinion we formed of this book on its first appearance. It is beautifully illustrated and clearly printed, and is one of the best works on obstetrics in the English language.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXVIII., No. 1. Pp. 1-132. January, 1925.—The Mechanism of Hæmolysis by Complement Action, by A. Hill and G. Parker (Shanghai). An experimental hypothesis of the intimate relations of red cells, immune body, and complement in a hæmolytic system which will hardly be followed by any but real mathematicians. The upshot of it is, in common language, that hæmolysis is ascribed to complement acting intracellularly in the period between its entrance into the cell and its combination with cell constituents, both entrance and combination taking place under the influence of immune body. In this period complement acts as a catalyst, encouraging the release of hæmoglobin by a ferment in the immune body more and more of which is set free with the progress of the hæmolysis. The final fixation of the complement is due to its combination with some other constituent of the immune body.—The Deviation of Complement in the Wassermann Test, by A. Hill, R. N. McKnistry, and G. Parker (Shanghai). The principles of the preceding analysis of the inwardness of hæmolysis are applied to a new quantitative modification of the Wassermann reaction.—Regeneration of the Lizard's Tail, by C. Powell White (Manchester). The process of regeneration has been studied in a series of wild *Lacerta vivipara* caught in North Wales, which after autotomy had more or less regained their normal structure. Regeneration takes place from a growing point consisting of a mass of undifferentiated cells situated immediately beneath the epidermis at the apex. From this all the tissues are re-grown except the epidermis, which spreads along from the remaining edge and the nerves, which are derived from the last three pairs of roots in the stump. The muscles develop segmentally and in the end the spinal cord is represented by a simple epithelial tube like a long filum terminale and the vertebrae by a continuous unsegmented tube of cartilage.—The Serological Classification of the Tubercle Bacilli by Agglutination and Absorption of Agglutinins, by G. S. Wilson (Manchester) (see THE LANCET, Feb. 14th, p. 348.—The Oxydase Reaction in Acute Myeloid Leukæmia, by A. Piney (London). The oxydase reaction has generally been recognised as appearing in neutrophile leucocytes at the stage in

their development which is marked by the appearance of definite cytoplasmic granules. The observation that a positive oxydase reaction may be obtained in the pre-granular phase is shown to be due to the use of stains which are not the most effective in bringing out the granules.—Observations on Platelet Genesis, by S. P. Bedson and Mary E. Johnston (London). Anti-lymph gland and anti-endothelial sera have no effect on the blood platelets in vivo; anti-bone-marrow serum destroys most of them in the circulation without causing purpura, while anti-spleen serum destroys the platelets and produces purpura. The spleen does not normally produce platelets and its richness in platelet antigen is due to their accumulation there from the blood. By exclusion, the authors conclude that during extra-uterine life platelets are generated in the bone-marrow; they fail to find any fresh evidence to support their former view that the platelet is an independent element, and appear to be coming round to Wright's hypothesis of an origin from megakaryocytes.—Spirochaete-like Structures in the Cerebro-spinal Fluid of Experimental Animals, by D. K. Adams, J. W. S. Blacklock, and J. A. W. McCluskie (Glasgow). Deceitful spirillar structures are found almost constantly in the lateral ventricles of monkeys, rabbits, and guinea-pigs.—Spirochaetes in the Ventricular Fluid of Monkeys Inoculated from Cases of Disseminated Sclerosis, by the same authors. Real spirochaetes were found in two monkeys similar to those previously recorded from inoculated rabbits.—The Normal Differential Leucocyte Count in South African Natives, Chinese, and Others, by the late E. Emrys-Roberts (Cardiff). Compared with British students, all showed a relative lymphocytosis.—The Leucocytes in Osteitis Deformans, by A. Piney (London). Five cases all showed an increase in eosinophiles and basophiles.—Avian Tuberculosis in a Marsupial, by N. S. Lucas (London). Tuberculosis has apparently not been found before in a marsupial; the author records a case of infection with avian bacilli in a rufous rat-kangaroo from New South Wales in the London Zoological Gardens.—Multiple Microscopic Metastases in the Spleen in a Case of Liver-cell Carcinoma, by D. F. Cappell (Glasgow). There was unusually widespread bare-eye metastasis.—Variations in Immunity Response in Different Animals, by A. T. Glenn (Beckenham). From a variety of examples the caution is drawn not to found immunological conclusions on small series of experimental animals.—Interim Report of the Committee on Status Lymphaticus appointed jointly by the Society and the Medical Research Council. While asking for assistance in accumulating more data, the Committee publish their provisional conclusions, of which the most important is that there is no evidence to show that there is any connexion between the presence of a large glandular thymus and death from unexplained or trivial causes; as many large glands are found in young persons killed by violence as in those dying under an anaesthetic.

BRITISH JOURNAL OF OPHTHALMOLOGY.—November, December, and January, 1924–25.—We have already noticed W. J. Adie's article in the November number on Cataract in Dystrophia Myotonica.¹ The greater part of the November and the December numbers is occupied with recent investigations by means of the slit-lamp.—Basil Graves presents a report adopted by the Lang Clinical Research Committee on a bilateral chronic affection of the endothelial face of the cornea of elderly persons, diagnosed by the aid of the slit-lamp, which may or may not be the precursor of the affection described by Fuchs as "Dystrophia Epithelialis Corneae."—The December number contains the 1924 Doane Memorial Lecture of Harrison Butler on focal illumination of the eye with special reference to the clinical use of Gullstrand's slit-lamp with illustrations of the appearances presented by different varieties of cataractous

and subluxated lenses. Even without the use of the Gullstrand lamp much information may be obtained by carefully focusing a point of any strong light at different depths behind the cornea. This is not nearly so dazzling as diffused illumination, and so tolerant is the pupil to focused light that it is possible to examine with the narrow ribbon of the slit-lamp a patient with an inflamed photophobic eye who could not tolerate diffuse light of an intensity sufficient to reveal necessary detail. Harrison Butler is an enthusiast for the new method.—In the January number Henry Friedenwald and Jonas S. Friedenwald write on epithelial dystrophy of the cornea, connecting the affection described by Fuchs with that described in the November number by G. Graves.—There are also an article by D. J. Wood on ocular leprosy, well illustrated, and a note by A. S. Percival on the alteration of the power of the cylinder when used for close work, on which we recently published an annotation.

Reports and Analytical Records.

POST'S BRAN FLAKES.

(GRAPE NUTS CO., LTD., 5, CHANCERY-LANE, LONDON, W.C. 2.)

THIS preparation claims to be a mixture of bran flakes with other parts of the wheat berry and is one of the well-known class of ready-cooked breakfast cereals which appear to be gaining popularity in this country. When analysed the flakes were found to have the composition:—

Assimilable carbohydrates ..	69.3 per cent.
Moisture	9.6 " "
Fat	1.7 " "
Proteins	13.2 " "
Mineral matter	3.5 " "
Cellulose	2.6 " "

Calorie value per lb. 1608.

The carbohydrates consist for the most part of starch which has been gelatinised and flaked. It is to the cellulose and mineral matter present that the mildly laxative action claimed for the preparation is due. The calorie value is a high one and comparable with that of wheaten flour.

FRY'S PURE SOLUBLE COCOA.

(J. S. FRY AND SONS, LTD., BRISTOL.)

When analysed this cocoa gave the following results:—

Fat	25.1 per cent.
Moisture	4.2 " "
Total ash	7.0 " "
Water-soluble ash	5.5 " "
Alkalinity of water-soluble ash as K ₂ O	2.4 " "

These figures are typical of a high-grade "soluble" cocoa. This so-called solubility is due to the customary treatment with a small amount of alkali during roasting. As the subject of preservatives in foods is claiming considerable attention at the moment, a special search was made for sulphites, borates, and salicylates. The results were negative.

PLAYER'S "NO. 3" VIRGINIA CIGARETTES.

(JOHN PLAYER AND SONS, NOTTINGHAM.)

These cigarettes are cork-tipped and heavier than most of the Virginia cigarettes on the market, about 21 going to the ounce. The paper on each cigarette weighed 0.06 g., or about 4.5 per cent. of the weight of the cigarette. On analysis the following results were obtained:—

Moisture	13.0 per cent.
Ash	10.7 " "
Silica	1.5 " "

The tobacco is fine-cut and of good quality and the cigarettes burn evenly and not too rapidly.

¹ THE LANCET, 1924, ii., 1189.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 21, 1925.

SOME INTIMATE ASPECTS OF HUNTER.

THE opening pages of our issue this week are occupied with the Hunterian Oration delivered on Saturday last, Feb. 14th, by Sir D'ARCY POWER, before the Royal College of Surgeons of England. The Hunterian Orator approached his great subject from a particularly intimate biographical side, and as a result was able to give pathetic details of the physical disabilities under which the Father of modern surgery carried on his magnificent work during the last 25 years of his life. JOHN HUNTER died of widespread disease of the arterial system, the largest as well as the smallest arteries being involved, and there seems no doubt, after the minute and tragic story set down by the Hunterian Orator, that the cerebral symptoms from which he began to suffer after he had inoculated himself with syphilis in 1767 continued intermittently until his death in 1793. The whole of the picture, as vividly drawn by Sir D'ARCY POWER, becomes coherent when we read of HUNTER's pathological lesions alongside of the description of his mentality, while we remember the splendid range of his accomplishment. We can understand the devoted affection which he inspired in his pupils, and we can understand also how a man devoid of all tact, and ill-equipped in accurate phrasing or the arts of persuasion by speech or by letter, should have made bitter enemies; and it was a happy thought which inspired the exhibition during the Oration of a series of illustrations directly lampooning the venerated subject of the discourse. For often the advocatus diaboli proves himself a valuable biographer, in proof of which we may refer to Mrs. Piozzi, who in her venom threw light on the great JOHNSON, where the pious BOSWELL was silent.

In this way, that good hater, JESSE FOOT, by revealing the existence of a group of men who were rendered suspicious and jealous by the reiteration of HUNTER's merits, shows us that HUNTER often felt himself in contest with personal foes and knew himself to be the subject of limitless detraction at their hands. For this circumstance dictated the uncomplimentary attitude which he always adopted in his personal disputes. The water-colour drawings, which were exhibited by means of the epidiascope at the close of the Oration, were executed for FOOT by an artist named BEAUMONT, to accompany a scurrilous life of HUNTER, the preparation of which seems to have occupied the last 30 years of FOOT's life—he was a pamphleteering medical practitioner, 16 years HUNTER's junior. The sketches are not only skilful in detail but so consistent as to portraiture that to the eye of candour, as FOOT might have said, they appear both contemporary and correct. Three volumes of FOOT's history, thus extra-illustrated or "graingerised," are now in the possession of the Wellcome Historical Museum, and for the following information concerning them we are indebted to Mr. VICTOR PLARR, Librarian to the Royal College of Surgeons of England. "A note," he says, "by FOOT on the back of a ball programme, dated from Ilfracombe in 1823, disputes with one, DYER the publisher, as to the price to be

paid for the collection of illustrations, DYER claiming not less than £86, plus extras, and FOOT standing out for £78. How the matter was settled is not known. The pictures are not caricatures, but may be described as excellent uncivil likenesses. JOHN HUNTER first appears holding WILLIAM HUNTER's invitation to London in his hand, and labouring at rough farm carpentry. Then in the kind of Highland dress the English of that day supposed Lowlanders to wear, he bids good-bye to his old father at the ancestral farm. He is handed a big bag of bawbees, and looks a nice red-haired Scotch laddie. Doubtless, in common with others, FOOT resented HUNTER as an interloper from the Kingdom of Scotland. In a blue suit the young HUNTER is next seen repairing to the shop of a dentist and barber. He holds a hare punningly in his hand in allusion to Spence's stock of wigs, displayed with dentures in the shop window, and it is suggested that he forms a disreputable partnership with SPENCE. HUNTER now sheds his blue coat, becomes a successful surgeon, and appears as a typical grave figure in black, a flat black wideawake on his still auburn locks. He looks for all the world in successive sketches like a little curate—a curate of genius. FOOT, whose picture is inserted, appears by contrast stately, in blue coat and buff waistcoat and breeches. There is next a sketch of HUNTER's very bare surgery and consulting room, where he is seen malpractising on the small son of Sir ROBERT ROWLEY, bitten by a mad dog, and one of HUNTER's supposedly suppressed failures. In another scene the irate and stately PETRUS CAMPER advances with a horsewhip on HUNTER. Again, we see JOHN and WILLIAM HUNTER disputing across a table at the Royal Society in the presence of Sir JOSEPH BANKS, so hated by 'PETER PINDAR.' "

The learned librarian's comments thus bring us to the examples of BEAUMONT's pictures inserted in our text. One of these records that HUNTER builds a house in Leicester-square, and entertains the eccentric MARTIN VAN BUTCHELL, bearded and wearing a billycock, and mounted on a queer pony, to come and survey the premises. In another picture a golden calf is over the door and the approaching figure of EDWARD JENNER worships it—perhaps prophetically. In a third, HUNTER drives a pair of buffaloes from his Earl's Court house to Leicester-square and extends a friendly hand to a menagerie showman en route. A fourth is a vile rejoicing at HUNTER's sudden death in St. George's Hospital. HUNTER's face throughout the pictures is distinctive with prognathous jaw, pointed chin, lean cheeks, long sharp nose, and yellow natural hair. It is no small tribute to the fame of the philosopher that 30 years after his death FOOT knew that his enemy's personality would be recognised. This outburst of spleen had a result exactly opposite to its intent, revealing as it did to all men the welter of suspicion in which HUNTER moved and the magnificence of his triumph over it.

THE BACTERIA OF FOOD POISONING.

SINCE it has been ascertained that nine out of ten outbreaks of food poisoning are traceable to bacteria of the Salmonella group, the public have a right to ask that efforts should be made to prevent the infection of food by these organisms. The Ministry of Health has enlisted the co-operation of the Medical Research Council to this end, and while the actual paths through which the organisms find their way into incriminated foodstuffs still elude discovery, the results of an investigation subsidised by the Council clear away

several preliminary difficulties. A report¹ by Dr. W. G. SAVAGE in association with Mr. P. BRUCE WHITE throws light, not only on the identification and classification of bacteria of the *Salmonella* group, but also on their distribution in nature and on the effects produced in animals by infection with different types of organisms. All the members of this group are short sporeless bacilli with rounded ends, possessing flagella and exhibiting motility. They are Gram-negative, stain readily with ordinary dyes, and are bile-tolerant. Their principal cultural characteristics are good growth on agar and on gelatin, which is not liquefied, the production of acid and gas from glucose and mannite, and the inability to ferment lactose, saccharose, and salicin, or to produce indol. Classification of the types of organism which make up this group has been attempted by various observers on the basis of morphological and cultural characters, of serological properties, of the source of derivation, of the pathological reaction in man and other animals, and of protective specificity. The result has been great confusion and overlapping. Dr. SAVAGE and Mr. WHITE give good reasons for regarding the biological and serological characters of the different strains as the most satisfactory basis for differentiation, using the other properties as confirmatory factors. From the examination of 150 strains Mr. WHITE has differentiated ten main types, which correspond very closely with those identified and described by H. SCHÜTZE in THE LANCET (1920, i., p. 93), and the first part of this report is devoted to a discussion of their serological properties. The distribution in nature of these species and the type of disease they may produce in man as well as in animal hosts has been provisionally tabulated in the second part of the report. The common causes of food poisoning outbreaks are *B. aertrycke* and *B. enteritidis*. Of these the former produces disease in cows, calves, and rats, while the latter is a widespread cause of enteritis in mice, guinea-pigs, and birds; it is occasionally found in pigs and calves but does not occur commonly in rats. The Derby, Stanley, and Newport types can also cause food poisoning in man, but their distribution in nature is apparently much less widespread. The Stanley type has not yet been isolated from animals; the Newport type is unknown in animals other than dogs; and of the Derby type, which has been isolated from pigs, the exact disease-producing rôle is unknown. *B. suispestifer* is exceptional as a cause of food poisoning, requiring special conditions such as massive infection. The fact that of all these species *B. aertrycke* is the least specialised as regards animal hosts may well be related to its common association with food poisoning in man.

That bacilli so closely related in their biological affinities should yet have such different pathological significance is a matter of great interest. For example, *B. paratyphosus* B regularly causes paratyphoid fever in man and probably never produces acute food poisoning of the ordinary type; further, there is no evidence that it can set up disease in animals. *B. aertrycke*, on the other hand, never causes paratyphoid fever in man but commonly food poisoning, and is found not infrequently to be the causative agent of disease in animals. Dr. SAVAGE and Mr. WHITE have attempted, in the third part of their report, to throw light on these and other pathological differences by a study of the local action of different types of *Salmonella* bacilli upon the alimentary tract in experimental animals. Parenteral introduction of organisms has been used for certain experiments,

but in the main bacilli have been administered by the mouth, in order that the method of introduction may be comparable with that in the human victim of food poisoning. The majority of the feeding experiments have taken the form of a comparative study between *B. aertrycke* and *B. paratyphosus* B. Experimental evidence supports the view that the essential lesion in food poisoning is irritation of the alimentary tract by a toxic substance which the authors believe to be an internal secretion of the organism, and to be directly associated with the virulence of the strain. The irritant effect is most vigorously exhibited by those strains which are responsible for food poisoning outbreaks and is much less evident, though not entirely absent, in types such as *B. paratyphosus* B and C, which do not cause human food poisoning of the ordinary irritant type but set up a more general infection.

In a review of the relationship of some of the factors concerned in infection to food poisoning outbreaks and animal infections which concludes the report, it is noted that the serological classification coincides at many points with differences in cultural behaviour, distribution, toxicity, invasive power, and pathogenic behaviour, though a great deal more work must obviously be done before conclusive results are reached. Unfortunately, in all outbreaks of food poisoning, whatever the type of organism concerned, the clinical features are essentially the same. The symptoms are those of intense gastro-intestinal irritation, and the attack is probably localised to the alimentary tract in that large majority of cases in which recovery ensues. The low death-rate (about 1 per cent.) in a disease of such severity is attributed by the authors to its causation by organisms of intense toxicity but low invasive power. The implication of the *Salmonella* group in the outbreaks following consumption of toxic canned foods where no organisms can be isolated is regarded as highly probable. The experimental evidence bearing upon this question is certainly suggestive, but Dr. SAVAGE and Mr. WHITE do not offer it as conclusive. Indeed, throughout the report the utmost care is taken not to claim too much from animal experimentation. But the fact that the authors have made and will shortly report detailed investigations, epidemiological and bacteriological, of 100 actual recent outbreaks of food poisoning in this country is sufficient guarantee that their laboratory experiments are only auxiliary to observations of disease in man, and it is mainly by such well-balanced combination of observation and experiment that modern epidemiology progresses.

SCIENCE AND GOVERNMENT.

THE group of photographs of medical Members of Parliament in THE LANCET of Feb. 7th recalls to a correspondent an interesting discussion in *Nature* (Jan. 3rd, 1925) of the part taken—or rather not taken—by scientific men in the government of modern countries. Dr. A. D. LITTLE had addressed the Franklin Institute in Philadelphia on the anomaly that, although all the distinctive features of modern civilisation are due to the discoveries made by scientific men, yet nowhere is the governing and directing power in their hands. The premise is obviously wrong; modern civilisation has its moral as well as its material victories, and if it consisted of nothing but aeroplanes and wireless it would not be much worth bothering about. But the fact is true enough, and at first sight it is perhaps rather surprising, though a little reflection suggests that such

¹ Medical Research Council, Special Report Series No. 91. H.M. Stationery Office. 3s. 6d.

an arrangement is not as undesirable as it appears. Treating the question empirically, the writer in *Nature* points out that in fact we have no clear evidence that the majority of scientific men would be of any particular use in the conduct of affairs, or that the views of the Royal Society on international politics are worthy of any special consideration; which leads him to the general conclusion that the scientist is best occupied by sticking to his own job. General considerations seem to indicate the same answer. The scientific habit of mind consists essentially in adding up facts correctly, in doing arithmetic with real numbers so to speak, and if public affairs had to deal with material of like kind scientific experience and training could not but be helpful. But governments rarely deal with facts, they have to cope with near-facts and ideals and emotions and aspirations, and if these can be reduced to an appearance of objective reality (as may be possible for example in economics) can the result be described as better than approximate? Affairs, in short, provide just the same kind of problems as does practical medicine. The difficulties of diagnosis and the obstacles to the evaluation of therapeutic procedures dealt with recently by Dr. E. BRAMWELL¹ arise mostly from the ill-defined numbers which the physician has to add up. When a doctor has to deal with 2 and 5 he has no more difficulty in adding them up to 7 than any ordinary man, as the neurologists have shown. But as a rule he has a figure supposed to be somewhere about 2 to relate to another which may be anything from 3 to 7 and it is little wonder if the answer is only right within about 100 per cent. He cannot treat the question algebraically, he cannot even use statistical arithmetic; his patient is a concrete individual. And the man of affairs and physician alike have another difficulty which the scientist never has to meet—they have to do something, and that without immoderate delay. In scientific questions the answer has necessarily to wait until there is reasonable surety about the numbers which have to be added up and the correctness of the addition; and as the result is a new piece of knowledge which no one can miss any more than they can miss tomorrow's breakfast, no one is particularly worried at the delay. But if the problems of unemployment were treated in the same way, and by men whose minds had been trained to work in that way, some dissatisfaction would probably result. The truth seems to be that these questions of government are on the whole best dealt with by persons who have improved by experience and practice a natural inclination to consider approximate data and to make clever, perhaps inspired, guesses at the number which results from the addition of x to y , or, when that is impossible, to select a range of numbers which we may call a compromise. Medical men occupy a peculiar position in having a scientific training which culminates in learning how to reach sound conclusions from very imperfect data. In many ways this is a singularly appropriate preparation for public affairs.

THE HEALTH OF THE KING.

THE KING has been during the week suffering from an attack of influenza of the respiratory type. The general condition is improving, but it is too soon to expect any change in the bronchitis. The official bulletins, signed by Sir STANLEY HEWETT, Sir MILSOM REES, and Lord DAWSON of PENN are keeping the public informed of His Majesty's progress.

Annotations.

"Ne quid nimis."

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD.

It is now 25 years since Batten, Russell, and Collier gave the first general description of the nervous disease associated with pernicious anæmia, and a great deal of study has been devoted to the subject in the interval. The discussion which took place on Feb. 11th at the Neurological Section of the Royal Society of Medicine revealed the amount of work that is being done on it at present, and showed that some progress is being made in the fight. Dr. A. F. Hurst, who was the opening speaker, presented a very complete hypothesis of its ætiology. He first showed that the anæmia with which subacute combined degeneration of the cord had been associated in all the 21 cases of his series had been identical by every known test with that called Addison's or pernicious anæmia, and assuming that this was the anæmia invariably associated with subacute combined degeneration, he treated the ætiology of the two diseases together. The essential predisposing factor he believes to be absence of the hydrochloric acid of the gastric juice; if, in cases of achylia, oral or pharyngeal sepsis occurs, streptococci find their way down and implant themselves in the duodenum; there they develop their specific properties and produce two different toxins—a hæmolytic toxin and a neurotoxin—and according as one or the other of these is the more favoured by circumstances, pernicious anæmia or subacute combined degeneration dominates in the morbid state which ensues. Every step in this argument was supported by facts and figures. In pernicious anæmia and in subacute combined degeneration achylia has been found by Hurst and by Vanderhof and others in 100 per cent. of cases. That the achylia precedes the anæmia and the nervous disease, and is not merely an associated phenomenon due to the same cause, is indicated by several groups of facts; achylia has been found as much as 13 years before the onset of pernicious anæmia, and in other cases 12, 10 (twice), 7, and 6 years; pernicious anæmia has followed not only the common "constitutional" achylia, but also that produced by cancer of the stomach and gastrectomy; both pernicious anæmia and achylia may be familial and their association has been recorded in 15 different families; in one family the father had pernicious anæmia, and the three elder children, aged 10, 6, and 4 years, all had achylia; in another a woman and two of her daughters and a granddaughter all died of pernicious anæmia and the third daughter had achylia. The next step in Dr. Hurst's argument is supported by the presence of hæmolytic streptococci in the duodenum in cases of pernicious anæmia and of subacute combined degeneration; in 77 per cent. of a series of 42 such cases streptococci were obtained by means of the duodenal tube or by puncture of the duodenum at operation, while in 150 cases of various other diseases they were only obtained in 21 per cent.; the streptococci were hæmolytic in 17 out of the 19 cases of pernicious anæmia or subacute combined degeneration in which they were examined, and in the other two cases of subacute combined degeneration there was little anæmia; that these organisms gained entrance through the mouth does not need to be insisted on; glossitis was present in 85 per cent. of cases and pyorrhœa and tonsillitis were frequent.

Based on such evidence Dr. Hurst's theory cannot easily be gainsaid in regard to any case of subacute combined degeneration in which the anæmia is undoubtedly Addisonian. But other workers who are also seeing large numbers of cases have not had the same uniformity as Dr. Hurst in their findings. Dr. H. J. Macbride, who continued the discussion, gave an analysis of 199 cases collected by himself and

Dr. Carmichael from the National Hospital, Queen-square. In 40 cases, which they had personally observed during the last two years, free hydrochloric acid had been present in the gastric secretion in no less than 14, and of all the 199 cases only 26 per cent. gave a history of antecedent alimentary symptoms. Dr. Stanley Barnes, too, stated that free HCl had been found in nine of his 12 cases since 1922. Thus, in nearly half the cases of these two groups there had been no achylia. When we consider the great constancy with which achylia is found in pernicious anæmia (603 out of 613 collected cases in Hurst's table), it is open to grave doubt whether the anæmia in these other cases is the same entity as Addison's anæmia; there are some reasons for thinking that there may be another anæmia, closely allied to the true Addisonian but independent of achylia, and that either type may be associated with subacute combined degeneration of the spinal cord. Dr. Macbride and Dr. Carmichael, in a careful analysis of their cases, sought for other ætiological factors; they found in their patients a very high tolerance of thyroid, in some cases after death they found pathological changes in the testis, and they observed that in women subacute combined degeneration almost always came on at the menopause. They therefore suggest that endocrine disturbance may be an essential part of the disease. There was a general agreement on lines of treatment; hydrochloric acid to be given in large doses (3ii.) before meals to all patients with achlorhydria, eradication of sepsis, autogenous vaccines, arsenic, by the mouth or intravenously (N.A.B.), and in some cases blood transfusion. Both Dr. Hurst and Dr. Charles Hunter were able to record in cases of subacute combined degeneration associated with true Addison's anæmia great prolongation of life and recovery for several years from the nervous symptoms—the most encouraging results yet obtained.

METHYLATED SPIRIT AND ITS SUBSTITUTES.

WE noted recently in these columns (THE LANCET, Jan. 24th, p. 193) the modifications in the composition of methylated spirit, and commented on the use of isopropyl alcohol as a substitute. We have recently received some American isopropyl alcohol made from petroleum by-products, and it appears to be of excellent quality and practically indistinguishable from that made from acetone. In view of its high purity it is not surprising to find that recent publications¹ concerning its pharmacology give entirely satisfactory reports, so that there need be no hesitation in using it in the same way as the product obtained from acetone. The toxicity is not less than and not more than twice that of ethyl alcohol. It is a more powerful bactericide and antiseptic than ethyl alcohol towards the organisms so far studied (*Staphylococcus pyogenes aureus*, *Bacillus coli communis*, *Bacillus anthracis*, *Bacillus subtilis*, and acetic acid bacteria). It is effective in lower concentrations than ethyl alcohol, the most effective being 30 to 50 per cent. The technical product contains 91 per cent. of the alcohol by volume and 9 per cent. of water, and has a boiling-point of 80.4° C. and a specific gravity of 0.820 at 15° C., and a density of 0.816 at 20° C. It is obtainable under the name of "Petrohol" at 38s. per gallon for single gallons. Industrial methylated spirit free from the harmful denaturants and colouring matter found in mineralised methylated spirits is now also available for medical and surgical purposes, permission having been given by the Board of Customs and Excise for the sale of such spirit suitably denatured. "Antiseptic Surgical Spirit, B.D.H.," sold by the British Drug Houses, is colourless and has a pleasant refreshing odour, and contains a reliable non-poisonous mild antiseptic, and no harmful ingredients. Some of the denaturant, however, is thrown out of solution on the addition of water. It appears to be well-suited for use

as an evaporating cooling lotion in various forms of skin inflammation and for application to the skin for preventing bedsores. It is also recommended for cleaning and sterilising the skin preparatory to operations, and for sterilising surgical instruments, which it does not rust. It is obtainable at 10s. per gallon.

THE BICENTENARY OF GUY'S HOSPITAL.

Guy's Hospital, having reached the very respectable age of 200 years, during which period it has ministered to the afflicted with unceasing pains and care, the editors of *Guy's Hospital Gazette* have taken advantage of the occasion to issue a special number of their journal containing a short history of the hospital, together with an account of the various departments and societies which go to make up the hospital and its work. We congratulate them on the result of their labours, for the number forms a valuable record of a great and noble institution. The history of the hospital is given in an all too short paper by Sir William Hale-White, and the other contributions are all from the pen of experts in the particular subject in hand. There are many and varied illustrations which are all of interest, some of which, too, raise a smile by the quaintness to modern eyes of the dress, notably that of the group of nurses of 1865 and 1875. The proportionate space allotted to the various papers is justly spaced, except, to our minds, in one instance; the section given up to the hospital Rugby football club consists of 37 pages, while Sir William Hale-White's paper on the hospital's history only takes up 26. One of the most interesting articles is that dealing with the history of the Physical Society by Mr. J. M. H. Campbell, which contains, among other items, an exceedingly grisly story, the subject being hydrophobia. We are glad to note a panegyric upon that brilliant little journal the *Guyoscope*, now, alas, dormant. This special number is a happy thought and well carried out. The whole publication should be read by all laymen who take an interest in the well-being of their fellow creatures, for we expect that many of them have no idea of the manifold activities which go to make up the work of a hospital.

MOSQUITOES AND COCONUT PALMS.

THE breeding habits of mosquitoes have received a considerable amount of attention from medical officers, sanitarians, and entomologists for some time; but it will be news to many of them that several species breed commonly in the tops of coconut palms throughout East Africa. Dr. W. E. Haworth was acting as medical officer of health for the town and district of Tanga, Tanganyika Territory, in June, 1920, when he made this important discovery. It came about in this way. In spite of vigorous anti-mosquito measures it was noticed that the number of mosquitoes in the European houses of the town increased to an alarming degree, and that the insects for the most part were of the genus *Culex*, of which the corresponding larvæ could not be demonstrated in any surface water in the town at the time. These observations suggested that some uncontrolled breeding-place must exist, and suspicion fell on the tops of the coconut palms which adorn the picturesque town. An expert climber, one Sefu bin Mbwana, having been procured, he proceeded to climb the highest palms with ease by walking up the stem. Armed with a bottle and the hollow leaf-stalk of the pawpaw, he sucked the water which collects between the axil and the stem. In order to do so he had to sit astride the swaying leaf and force its stalk away from the stem—a highly sensational and perilous proceeding. In this manner no less than 10,382 palms were examined along the East African coast, at Kismayu, Lamu, Mombasa, Tanga, Zanzibar, Dar-es-Salaam, Mafia, Kilwa Kiswani, Lindi, and Mikidani. Twenty-seven species of mosquito were found breeding in palm water, including two species of *Anopheles*, 11 of *Aedes*

¹ D. H. Grant: *Journal of Laboratory and Clinical Medicine*, 1923, viii., 382; *American Journal of Medical Sciences*, 1923, clxvi., 261.

(formerly *Stegomyia*) and a large number of *Culex* of various species. The predominating form of mosquito was not the same at all stations. At Tanga it was *Culex fatigans*; at Dar-es-Salaam *Aedes (Stegomyia) argenteus*; possibly in some places the more dangerous malaria-carrying *Anopheles* may abound to the same degree. The number of mosquitoes proceeding from this source are most certainly a source of danger to the community. Granted even that only a few perfect insects emerge daily the total number thus produced must be a very considerable one when the number of palms, which may exceed 70,000 in one township area, is considered. What has been demonstrated¹ for one portion of East Africa probably holds true for all coconut-growing areas throughout the tropics, and the importance of this subject from a public health point of view can hardly be overestimated. Dr. Haworth is to be congratulated on a piece of work which suggests that the task of eradicating the mosquito in tropical districts is more difficult and complicated than has been apprehended. It must be a source of especial satisfaction to him that three handsome new species of the genus *Aedes* have been discovered as the result of this investigation. Excellent figures of these three species—*A. haworthi*, *A. calceatus*, and *A. soleatus*—which are described and named by Mr. F. W. Edwards in an appendix, have been drawn by Mr. A. J. E. Terzi to illustrate Dr. Haworth's survey.

VOLUNTARY AID DETACHMENTS: PROGRESS OF THE SCHEME.

THE King has graciously permitted the Royal Crown to be included in the badge for mobile members of the Voluntary Aid Detachments. Already over 200 men's and women's detachments have been formed and received official recognition. These detachments have been raised by the St. John Ambulance Association, the British Red Cross Society, and the St. Andrew's Ambulance Association. County Controllers have been appointed in nearly every county in England, Scotland, and Wales, and a Scottish and a Welsh Committee have been formed with headquarters in Glasgow and Cardiff respectively. These Committees are responsible to the Central Joint Voluntary Aid Detachment Council for the administration of the new scheme in those areas. The scheme was evolved in 1923 out of war experiences, when it was decided to reconstitute the Central Joint Voluntary Aid Detachment Committee formed during the war to administer Voluntary Aid Detachments. As it now exists, the scheme is designed to supplement the Medical Services of the Naval, Military, and Air Forces on emergency in any part of the world, and the various Territorial Army Associations are responsible for the enrolment and organisation of V.A.D. members. Members are now being trained for eight days in Naval, Military, and Air Force hospitals, and "Training Regulations" have been issued and classes of instruction are being held in most centres and districts.

THE SERUM PROPHYLAXIS OF MUMPS.

ALTHOUGH mumps is not a severe disease in its typical form, outbreaks of this infection in institutions for children and aggregations of adolescents and adults may cause considerable inconvenience and loss of time to the individual and the community as a whole. Joseph C. Regan² has therefore made trial of prophylactic injections of convalescent serum, a method which has been employed with such striking results in the prevention of measles on the continent and in America, though it does not appear to have been much tried in this country. Six groups of children, amounting to 81 in all, who had been exposed to

mumps at different times in the Kingston Avenue Hospital, Brooklyn, were injected with the serum of convalescents from the disease, the doses varying from 2 to 4 c.cm. The donors were healthy adults who gave a negative Wassermann reaction, were clinically free from any signs of active tuberculosis, and were between the tenth and twentieth, and usually between the fourteenth and sixteenth day of disease. Only one of the children so treated developed mumps, but it should be noted that 11 were discharged from observation before the incubation period was over, and their subsequent history was not known. Dr. Regan suggests that in order to modify the disease and particularly to avoid orchitis without preventing the occurrence of the disease altogether the serum should be injected late in the incubation stage and in somewhat larger doses than he has recommended for the other cases. A more lasting and possibly permanent immunity is conferred by an abortive attack of mumps, whereas the immunity afforded by early injection of the serum is only transient.

CANCER RESEARCH BY THE GENERAL PRACTITIONER.

A MONOGRAPH published as a supplement to *Norsk Magazin for Lægevidenskaben* for December is an example of what a general practitioner may do as a research worker even in these days of laboratories and instruments of precision. The author, Dr. Just Thoner, has practised in a mountainous district in Norway (Gol and Hemsedal) from 1907 to 1921, and throughout this period he has consistently pursued certain investigations of cancer as it occurred in this remote district whose population has been remarkably stationary. Dr. Thoner made himself familiar with the family history of every home in the two parishes in which he worked, and he collected 120 cases of cancer occurring in the period 1902-21 in an area with an average population of 3679. Of the 120 cases, as many as 73 were males, and the site of the cancer was the alimentary tract in 61 per cent. of the total. There was only one case of carcinoma of the uterus, but as great a proportion as 14 per cent. of the total were cases of sarcoma. About 50 per cent. of the cancers occurred between the ages of 60 and 80 years, and after the age of 80 there were hardly any such cases, and it would seem that, in this country district, cancer is not so much a disease of advanced age as of "incipient senility." External causes seemed to have played a part in 42 per cent., trauma alone in 19.5 per cent. of all the cases. Cancer affecting both husband and wife was observed in only 5 to 6 per cent. of the married patients, and the interval between the cancers of the husband and wife was often long—up to 25 years. Even in the homes where a cancer was associated with a profuse discharge, and cleanliness was conspicuous by its absence, it was rare to find an accumulation of cases within a short period, and Dr. Thoner concludes that "the transference of cancer from one individual to another must be rather rare if taking place at all. . . ." With regard to the influence of heredity, Dr. Thoner was able, thanks to the stationary and rural character of his material, to show that, in comparison with tuberculosis and insanity, cancer certainly does not seem to show a marked preference for certain families. But his investigation of the records of five "cancer families" showed that, if only the deaths over 35 be considered, the cancer incidence of these families was 18.2 per cent., as compared with 12.1 per cent. for the total population. Many other interesting facts, such as the geological formation of the districts concerned, the changes in the diet of the population during the past century, and the character of the daily life led by this comparatively isolated community, are discussed by Dr. Thoner, whose work has been financed by the Elizabeth and Knut Knutsen's Fund for Cancer Research. Included in his 155-page monograph is a summary in English. It is to be

¹ Mosquitoes and Coconut Palms—A Mosquito Survey of Palm Trees in East Africa and the Problems Resulting Therefrom. By W. E. Haworth, M.B., C.M., B.Sc., Trans. Roy. Soc. Trop. Med. and Hyg., 1924, October, vol. xviii., No. 4, pp. 162-198.

hoped that the example set by Dr. Thoner will be followed by others, and that work of this kind will not be financially starved on the assumption that research is a monopoly of the laboratory.

THE IRISH FREE STATE AND THE MEDICAL REGISTER.

THE Senate of the Irish Free State recently passed the Medical Bill, dealing with the maintenance of the Medical Register, through all its stages, and the Bill has now become law. The Bill authorises the General Council of Medical Education and Registration to continue to exercise authority in respect of medical practitioners in the Irish Free State. Persons registered under the Medical Acts are, in the Free State, to have the same rights, privileges, and immunities, and be subject to the same obligations as in Ireland before the Free State came into existence. The General Council is to have, in relation to persons and matters in the Free State, all the old powers, jurisdictions, and authorities; the Branch Council for Ireland will similarly retain its powers; the General Council and the Branch Council will continue to be constituted and elected as before; and Universities and medical corporations in the Free State continue to have powers of granting diplomas and holding qualifying examinations under the Medical Acts. The Bill is for the period of one year. Mr. McGilligan, Minister for Industry and Commerce, who was in charge of the Bill, stated that prolonged negotiations had taken place between the British and Irish Governments in reference to some points in dispute. For the next 12 months, however, the position of medical men qualified in the Free State is assured, in that they will continue to enjoy equal privileges with their colleagues in the United Kingdom and Northern Ireland.

THE DANGERS OF EARTHENWARE COOKING UTENSILS.

A VARIETY of types of saucepans, frying pans, and casseroles have been recommended from time to time by health enthusiasts, but the dangers of each have been unmasked by a relentless series of chemical investigations. Thus enamel vessels have been condemned because it has been stated that such lesions as appendicitis may result from the swallowing of small pieces of dislodged enamel. Nickel-lined utensils have also been included¹ in the danger list, since, although stable to alkaline fluids, they are unsuitable for acid foods, such as stewed fruits and the like. Aluminium² and zinc³ containing alloys have also proved to be unsuitable for the manufacture of cooking utensils. Iron and steel rust, and consequently earthenware goods have been looked upon as a last resort, and have, up to the present, been regarded as being safe. A report just issued by the Ministry of Health (Reports on Public Health and Medical Subjects, No. 29)⁴ proves conclusively that we must inquire carefully into the history and birthplace even of our casseroles and earthenware vessels before entrusting our meals to them. In this report Dr. G. W. Monier-Williams calls attention to the danger of absorbing noxious substances from the glaze of these articles. The report, which, although highly technical, is extremely interesting, commences with a brief outline of investigations already performed upon the question of lead poisoning arising in connexion with lead glazing. As Dr. Monier-Williams points out, practically all these investigations were conducted from the point of view of danger

to the workers during the actual process. Briefly, the process consists in "fritting," or fusing a mixture of red lead, clay, ground flint, and washing soda in a kiln. A mass of lead silicates is thus produced. The "fritt" is then ground up and suspended in water in which the vessels to be glazed are dipped. The vessel is then baked at a high temperature in order to produce a uniform glossy surface. As early as 1887 the Germans realised that such glaze might liberate lead if boiled with acid solutions, and they laid down a law that condemned any cooking vessel yielding lead on boiling with 4 per cent. acetic acid. The object of Dr. Monier-Williams's researches was to reinvestigate those problems, and to determine the stability of glazed articles to ordinary cooking processes. His results may be summarised by stating that certain wares do give off lead, arsenic, and other toxic substances when submitted to the ordinary cooking processes, and that consequently they are a source of danger. We gather from the report that the most unsuitable articles come from abroad, or from the smaller English potteries.

The question naturally arises as to what sort of cooking utensil really is safe. In view of the unsuitability of most ordinary materials, a new form of extravagance in the shape of platinum-lined casseroles suggests itself for delicate millionaires.

THE zeal inspired by Sir James Mackenzie will not cease with his death. It would be unfortunate indeed if the work which he initiated at St. Andrews should have to be discontinued through lack of funds, especially since the ultimate value of observations by a group of practitioners must depend largely on the length of time covered by their records. A suggestion that a fitting tribute to his memory would be the endowment of the Institute founded by him at St. Andrews is likely to receive cordial support. We understand that £60,000 is the minimum sum required if the James Mackenzie Institute for Clinical Research, St. Andrews, as it is now to be called, is to be put on a sound financial basis. Of this sum £7000 has already been collected. Donations should be sent to the hon. treasurer of the Institute, Commercial Bank, St. Andrews.

INTERNATIONAL CONGRESS OF THALASSOTHERAPY.—The fourth International Congress of Thalassotherapy will be held at Arcachon, near Bordeaux, from April 27th to 29th. The Association of Thalassotherapy (treatment of disease by a residence at the seashore, by sea-bathing, or by a sea-voyage) was founded by Prof. Verneuil, of Paris, at the International Congress at Boulogne in 1895. The President of the Association was for many years Prof. Albert Robin, of Paris, Member of the Academy of Medicine, and the presidency is now held by Prof. Gilbert, of the Paris Faculty of Medicine and a Member of the Academy of Medicine. The Association is managed by a permanent bureau with its office in Paris. This permanent bureau, together with the national committees of each country, organises the international congresses. Among the French Committee are many well-known names, such as Prof. D'Arsonval, Prof. Marfan, Prof. Pinard, and Prof. Roger, Dean of the Faculty of Medicine of Paris. Dr. Robert Pierret has been elected liaison secretary to assist the work of the British Committee, among whose members are Sir Dyce Duckworth, Sir Humphry Rolleston, and Sir St. Clair Thomson (President of the British Committee), and Dr. Campbell McClure (secretary). The question to be discussed at the forthcoming International Congress is the Marine Treatment of Rickets. The speakers from Great Britain will include Prof. Leonard Hill and Dr. P. L. Webster, and delegates from France, Italy, Belgium, and other countries will also contribute papers to the discussion. The Association is composed of titular and adhering members and the subscription for the Congress is fixed at 50 French francs for the titular members and 30 francs for the adhering members. Special facilities for accommodation at Arcachon have been secured at reasonable rates. All the members who intend to be present at the Congress are requested to write to Dr. Pierret, 7 bis, Rue Raynouard, Paris (16e) from whom further information may be obtained.

⁴ Reports on Public Health and Medical Subjects, No. 29. The Solubility of Glazes and Enamels Used in Cooking Utensils. By G. W. Monier-Williams, M.A., Ph.D., F.I.C. London: H.M. Stationery Office, 1925. 6d.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CX.—THE TREATMENT OF TWO CHRONIC SKIN DISEASES.

II.—ACNE VULGARIS.

Acne vulgaris is sometimes regarded as a trivial complaint which will right itself as the patient gets older. But it is a disfigurement even in its mildest forms and may if neglected take on a more serious aspect. It may last over a number of years and lead to permanent scarring. It should, therefore, never be left to take its own course in the hope that it will eventually clear up without treatment. Acne vulgaris is a disease of puberty and of early adult life. Its essential feature is the comedo or "black-head," without which there cannot be acne. The comedo was supposed formerly to be due to a blocking of the mouth of the pilo-sebaceous follicle by dried sebum and immature hairs. It is really a dense mass of acne bacilli enclosed in a sheath of horny epithelial cells which have been thrown out by the epidermis as a protection against the bacillus. The acne bacillus is not found on the skin until puberty, and the theory which best explains its presence at puberty is that the sebaceous glands then become more active and thus form a suitable soil for the acne bacillus which flourishes on an oily skin. Greasiness of the skin in the areas affected is an early and constant feature of acne. When only the oily skin and the black-heads are present we have "acne punctata." A further stage is presence of papules and of papulo-pustules. Each papule or papulo-pustule is formed around a comedo, and is due to a secondary infection by the *Staphylococcus epidermis albus*, or more virulent forms in more severe cases.

It will thus be seen that the rational treatment of acne is to begin in the earliest stages to try to control the oily state of the skin and to remove the colonies of acne bacillus from the mouths of the follicles. In most cases the time-honoured method of soap and hot water and sulphur lotion is successful if carried out thoroughly and with perseverance over weeks or months. The face should be soaped every evening, for two or three minutes by the clock, using a face towel or a shaving brush. It should then be bathed with hot water and a sulphur lotion rubbed on with a piece of absorbent wool and allowed to dry on. When the skin gets a little rough and sore the treatment should not be discontinued but should be merely omitted for a few evenings and glycerine of starch applied at bed-time. It is sometimes advised that the comedones should be expressed, but this should never be done by the patient and, if at all, only by the medical man. An ordinary toilet-soap may be used for the soaping or a sulphur soap. A suitable sulphur lotion is:—

R	Sulphur precip.	..	..	oz. $\frac{1}{2}$.
	Glycerini	..	..	dr. 2.
	Tinct. quillaie	..	..	oz. $\frac{1}{2}$.
	Spirit. coloniensis	..	..	dr. 1.
	Aq. destil.	..	..	ad oz. 6.

In cases where there are papules and pustules the same treatment may be employed, with the addition that any pustule should be broken with a pointed match stick dipped in tinct. iodi before using the soap and sulphur lotion. Where there is much pustulation a sulphur and resorcin paste may be applied at bed-time instead of a sulphur lotion, thus:—

R	Sulphur	..	..	gr. 15.
	Resorcin	..	..	gr. 10.
	Pulv. amyli	..	..	dr. 3.
	Vaseline	..	..	ad oz. 1.

Internal Medication.

Although acne vulgaris appears to be due to an external infection and there is really no evidence that an internal cause has to do with its origin, it is generally taught that anæmia, constipation, indigestion, or improper feeding are important factors, and arsenic or iron tonics and saline aperients are often prescribed. A favourite mixture is the classical Startin's mixture of iron, magnesium sulphate, and acid sulphuric. Calcium sulphide may be given internally, gr. $\frac{1}{2}$ — $\frac{3}{4}$, with the view to control suppuration, or some preparation of yeast with the same object. But reliance cannot be placed upon these internal remedies, and vigorous and persevering external treatment must not be neglected with the hope of curing by more general measures.

Associated Seborrhœa Capitis.

An important practical point is that most cases of acne are associated with seborrhœa capitis, with greasy scales and sometimes loss of hair. The acne bacillus is found in the scales and it is probable that continued infection of the face may take place from the scalp. To overcome this condition the head should be shampooed once a week with a spirit soap as follows:—

R	Saponis kalni	..	..	oz. 3.
	Spirit. vini meth. vel rect.	..	..	oz. $\frac{1}{2}$.
	Spirit. lavandulæ	..	..	dr. $\frac{1}{2}$.
	Aq. dest.	..	..	ad oz. 6.

The head is made wet with warm water and lathered with ordinary toilet-soap. A few teaspoonfuls of the soap solution are then poured on to the scalp and the lathering continued for several minutes, and the lather is then rinsed off with clean water.

Of recent years two new methods of treating acne have been employed—namely, vaccine treatment and X ray treatment.

Vaccine-Therapy.

Vaccine treatment of acne, although occasionally very successful, is uncertain in its results, so that one may hesitate to prescribe what must be a long course of treatment without any assurance of a good result. It is seldom, if ever, successful in acne punctata, and even where there is pustulation it frequently fails. It is, therefore, rather a remedy to use as a last resort or in addition to other measures than as a routine. Autogenous vaccines are more likely to succeed than stock vaccines.

X Rays.

In X rays we have a very valuable addition to our methods of treatment. It is always of great assistance, and, generally, very successful in at once clearing up the eruption or of considerably shortening its duration. It is sometimes avoided as a dangerous remedy, and it is so if not carefully applied; but with proper precautions it is entirely free from any risk of damage to the skin. This does not imply that any medical man who employs an X ray apparatus, however skilful he may be in radiographic work, is necessarily competent to treat safely a case of acne by X rays. He must have also experience in therapeutic dosage. Probably those only who have experience in the treatment of ringworm by X rays are able to appreciate fully the true meaning of an accurate dose; and there are many radiologists throughout the country who have now had this experience at the numerous ringworm treatment centres. X ray treatment may be employed even in quite early cases of acne punctata, and with excellent results. In more advanced pustulating acne, X ray treatment always shortens the cure. In cases of acne indurata with deep-seated indurations and pustules, no other treatment is so successful. In regard to the manner of application of the X rays there is a difference of opinion. Some prefer to give repeated small doses, others larger doses less often. But since there is no improvement

until by repeated small doses we reach by their cumulative effect that of a large dose, it is really safer to employ the larger dose at once, because it can be more accurately measured than can the cumulative effect of many small doses. A dose which is quite free from danger is a 2/3 Sabouraud pastille dose, and this may be safely repeated in three weeks, and after the second dose, at intervals of four weeks. In order to expose the whole face three doses are given, one to the forehead and one to each cheek. The hair at the scalp margin and the orbits, including the eyebrows, are covered with thin lead shield protections. Improvement is seen in from ten days to three weeks after each application. In some cases one or two applications are sufficient; in others, the treatment must be continued at intervals of four weeks or longer, sometimes for many months. Where in spite of a general improvement, fresh pustules continue to appear, we may supplement the treatment by a course of autogenous vaccines. Acne of the back and shoulders or chest may receive the same treatments as acne of the face.

Acné Excoriée.

It has already been mentioned that scarring is a common sequel of pustular acne. The patient should be warned of this lest the treatment by X rays or by other methods be afterwards blamed for the scarring. Scarring, sometimes quite extensive, may be produced in another way than by the healing of pustules. A patient who has acne and particularly a female patient, may acquire a habit of squeezing, pinching, or tearing with the nail every little acne spot, and may sometimes spend much time in front of a looking-glass performing this operation. Eventually, it may happen that even in slight cases this pinching, squeezing, and scratching becomes an almost unconscious habit which continues for long after there have ceased to be acne spots. Each erosion so produced not only causes present disfigurement but subsequent scarring. Such cases have been called by French writers "acné excoriée," and in cases of acne in a girl or young woman which seems to resist all treatment this cause should be considered. It will often be found that there is really no acne—no comedones and no papulopustules—but only dug-out excoriations and scars. In such cases it is generally merely necessary to convince the patient that the lesions are entirely due to her own interference and that she has only to refrain from touching her face with her fingers in order soon to bring about a cessation of the supposed acne eruption.

H. G. ADAMSON, M.D., F.R.C.P. Lond.,
Physician for Diseases of the Skin, St. Bartholomew's
Hospital, London.

THE Minister of Health has appointed Mr. Howell E. James, senior assistant secretary, Welsh Board of Health, to be secretary of the Board in succession to Mr. Percy E. Watkins, who has been appointed permanent secretary of the Welsh Department of the Board of Education from April 1st, 1925.

EUGENICS EDUCATION SOCIETY.—A lecture on Mate Selection in Primitive Society will be delivered by Mr. B. Malinowski, D.Sc., at the rooms of the Royal Society, Burlington House, Piccadilly, London, W., on Feb. 27th, at 8.30 P.M. Major Leonard Darwin will preside. All interested in the subject are invited to attend.

ROMFORD AND DISTRICT MEDICAL SOCIETY.—The first annual dinner of this new society was held at the White Hall Hotel, Romford, recently and was presided over by the President, Dr. J. H. Bletsoe. The society has already a substantial membership and the Romford Board of Guardians have granted the use of their board room for the meetings, which are to be held bi-monthly. At the annual dinner the guest of the evening was Sir John Bland-Sutton, who replied to the toast of "The Visitors," submitted by Dr. Charles D. Green, one of the oldest medical practitioners in the district. The Vicar of Romford, Rev. H. C. Robins, replied for the lay visitors. The toast of "The Society" was proposed by Mr. Alan Todd, and suitably acknowledged by the President.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

HUNTERIAN FESTIVAL DINNER.

FOLLOWING the delivery in the afternoon on Saturday last, Feb. 14th, by Sir D'Arcy Power, of the Hunterian Oration, the Hunterian Festival Dinner was held at the Royal College of Surgeons of England, Sir John Bland-Sutton, the President, presiding. The following were present:—

Mr. J. H. Whitley (Speaker of the House of Commons), Lord Hewart (Lord Chief Justice of England), Sir Charles Sherrington (President of the Royal Society), Sir Frank Dicksee (President of the Royal Academy), Mr. Raymond Apperly, Mr. S. G. Asher, Sir James Atkin, Dr. Andrew Balfour, Mr. Sheriff Barthorpe, Mr. James Berry, Sir John Bland-Sutton, Sir Anthony Bowlby, Sir William Bragg, Dr. A. D. Brencley, Mr. R. H. Burne, Viscount Burnham, Mr. Alastair Cameron, Mr. H. S. Clogg, Sir Frank Colyer, Mr. S. F. Cowell, Earl of Desart, Mr. Sheriff Downer, Sir Frank Dyson, Mr. W. McAdam Eccles, Mr. C. H. Fagge, Mr. J. Herbert Fisher, Dr. H. Morley Fletcher, Maj. Stanley Flower, Sir Archibald Garrod, Mr. G. E. Gask, Sir Rickman Godlee, Lt.-Gen. Sir John Goodwin, Sir Charles Gordon-Watson, Mr. Justice Greer, Mr. H. A. Gwynne, Mr. J. Basil Hall, Mr. F. G. Hallett, Mr. W. Sampson Handley, Sir Robert Hudson, Mr. R. Johnson, Sir Arthur Keith, Mr. Rudyard Kipling, Mr. T. W. P. Lawrence, Mr. T. P. Legg, Lt.-Gen. Sir William Leishman, Mr. H. Lett, Mr. V. Warren Low, Sir Richard Luce, Sir George Makins, Merchant Taylors' Company, Sir Henry Morris, Sir Berkeley Moynihan, Sir David Murray, Mr. J. Murray, Rev. J. A. Naim, Sir George Newman, Mr. J. L. Payne, Sir Edward Pearson, Mr. H. S. Pendlebury, Mr. V. G. Plarr, Sir D'Arcy Power, Squadron Leader D'Arcy Power, Press Association, Mr. L. B. Rawling, Sir A. W. Renton, Lord Riddell, Sir Humphry Rolleston, Mr. R. P. Rowlands, Dean of St. Paul's, Salters' Company, Col. H. S. Sankey, Mr. Percy Sargent, Mr. James Sherren, Col. T. Sinclair, Mr. W. G. Spencer, Mr. E. Sprawson, Sir Squire Sprigge, Lord Stanmore, Mr. F. J. Steward, Sir Charters Symonds, Prof. A. Thomson, Sir StClair Thomson, Sir Cuthbert Wallace, Sir Holburt Waring, Mr. A. E. Webb-Johnson, Sir Dawson Williams, Prof. William Wright.

At the close of dinner the President proposed The Memory of John Hunter, when the toast was drunk standing and in solemn silence.

The Lord Chief Justice proposed the Royal College of Surgeons and claimed that nothing could possibly exceed the debt which man owed to surgery and to law. In some humorous musings upon the comparative antiquity of the two professions he said that, if medicine could be called as old as the first baby, the law might well be older, for it might be that in the Garden of Eden, before the first medical interference had been necessitated, questions had arisen concerning the law of husband and wife or landlord and tenant. He indicated one great difference between the professional life of the lawyer and that of the surgeon, which was that the lawyer was not suddenly called upon in a case which seemed likely to be fatal to do the best that he could on the spur of the moment with the knowledge that death might follow and, it would seem, with the risk that he might be prosecuted for negligence.

Sir John Bland-Sutton, in acknowledging the toast of the College, said that the nexus between the profession which the surgeons humbly followed and that which Lord Hewart so eminently adorned was, from the surgeon's point of view, as direct as the hangman's rope, explaining his reference by the well-known fact that in years gone by the satisfaction of justice provided the anatomical subjects for the London schools. The President then brought to the attention of the audience the deep interest which Hunter had taken in bones and teeth, and mentioned that Hunter's first book dealt with the natural history of the human teeth and was written, according to report, in order to defray the expenses of his wedding

Sir Holburt Waring proposed the toast of the guests, reminding them of the personality of Martin van Butchell, whose caricature they had seen in Beaumont's sketches, and whose mummified wife was in the College Museum. He coupled with the toast the Speaker of the House of Commons.

The Speaker suggested in reply that his presence at a dinner of surgeons might be due to a conspiracy, for he knew that there were some 600 Members of the House of Commons who would like to have an operation performed on his eye. But if any such operation were contemplated he thought that there might be difficulties, because each of the 600 Members would demand that the organ should be made to point in a different direction.

The Rev. Dr. Nairn, Headmaster of the Merchant Taylors' School, proposed the health of the Hunterian Orator, explaining that he did so from the point of view of personal regard as well as from that of admiration of the Orator's talents, as not only was Sir D'Arcy Power educated at the Merchant Taylors' School, but he had sent two of his sons to follow him at that institution. Sir D'Arcy Power, having briefly replied, the company were invited by the President to visit the various departments of the College, where great interest was expressed in a new portrait lent for the occasion by Mr. Buckston Browne.

A New Portrait of Hunter?

The portrait is attributed, probably with good reason, to Gainsborough. This is a John Hunter entirely different from the dreamy and noble portrait by Reynolds, or from the pawky but admittedly excellent profile by Holland, yet strikingly like the Hunter in a brown coat hanging in the outer hall of the Royal College of Surgeons of England. The upper part of the face, with slightly tilted left eyebrow, and tilted leftward more in the alleged Gainsborough, is fairly identical with the same feature in the brown Hunter. The right eye in each portrait shows a slight squint. The brown Hunter has a keen brown eye, the Gainsborough a dull grey eye. Moreover, the lower part of the Gainsborough face is full; nothing suggests the concave conformation of the jaw. Have we indeed here a portrait of John Hunter, physician, the great Hunter's contemporary, known for his excellent treatise on anthropology and his books on military hygiene in Jamaica? The Gainsborough man points at the skull of a great ape, but Doctor John Hunter as an anthropologist might have done so, quite as much as John the surgeon.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

THE PROVISION OF MEDICAL BENEFIT.

*Evidence by Mr. Brock and Dr. Smith Whitaker
(continued).*

Records of Illness.

(App. C. 71-81.) The form of record of illness which every insurance doctor is now required to keep is based on the recommendation of a Departmental Committee presided over by Sir Humphry Rolleston. It provides for a continuous record of an insured person's sickness and is passed, when he removes, to the doctor in his new district. (Q. 1214, 1215.) The Committee considered that the object of helping the doctor in the treatment of a case was paramount, but the record is also intended to serve useful statistical purposes. It has never been considered that it would

* In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247-8); The Provision of Medical Benefit (Feb. 7th, pp. 301-3; Feb. 14th, pp. 355-6). References to the official statement which has been issued as an appendix in four sections are given thus: Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

be possible, consistently with having a continuous record kept by the doctor, to gather up all the records periodically and make a general statistical analysis, but sample investigations are possible, and to some small extent—up to the present—this has been done.

(Q. 1243.) In reply to a question it was stated that officers of the Ministry could, if required, make a limited investigation for the purposes—e.g., of the Industrial Research Board. A further question related to the possibility of a limited number of doctors keeping fuller records for the purposes of a special investigation. As to this, it was stated:—

(Q. 1288.) We derived some assistance of that kind in the Rheumatism Inquiry. There was very little satisfactory information as to the existence of different types of rheumatism, and, guided by the way in which the records were kept, practitioners were selected whom we could regard as reliable men to keep a special record with regard to rheumatism. Forms were issued to them and they kept a record of all cases treated within twelve months of any kind of condition that might broadly be called rheumatic. Those returns were of great value.

How the Records are Being Kept.

(Q. 1282.) When the present records were first started some difficulties were experienced in getting them properly kept; these difficulties were attributed by the witnesses to inexperience, to the agitation by some people against the records, which prejudiced the doctors against them, and to the natural reluctance of most medical men to do any clerical work that they can avoid. (Q. 1285.) The regional medical officers of the Ministry, who have the duty of examining records, all report a changed attitude on the part of the general body of practitioners towards the records. A large number of doctors say that they find the records helpful both in the treatment of cases which have been in their hands all through and in the treatment of cases that come to them from other doctors.

Size of Doctor's List—Number of Services Rendered.

(Q. 1219-1225.) The witnesses were asked to say on the basis of a list of 2500 insured persons how many patients a doctor would see in the course of a day's work. They said that on the 1923 figures it was found that a doctor saw about 50 per cent. of the persons on his list. On the average, actual patients are seen seven times, so that the doctor has to render 3.5 services per annum for each person on his list. With a list of 2500, this works out at about 29 services a day. Of these 29 services, probably eight in an urban area would be domiciliary visits; the remaining 21 would be surgery attendances. Taking a normal urban practice a doctor could do between three and four visits an hour. As regards surgery attendance, of those 21 persons attending at the surgery on the average, only three are coming for the first time, and, therefore, may be expected to require a fairly careful examination; the remainder are coming back either to report progress, or to ask for another bottle of medicine, or to obtain a sickness certificate, and those cases can be worked off pretty rapidly. If an hour is allowed for the three new cases, the others could probably be worked off at nine or ten to the hour. These are average figures, and only true of urban areas. In rural areas the proportion of visits to attendances is quite different.

The following figures as to the sizes of lists in England and Wales are of interest—35 per cent. of the total have lists of 600 or under, 30 per cent. have from 600 to 1200, 21 per cent. have from 1200 to 2000, and only 14 per cent. have more than 2000. Of that 14 per cent. a majority, probably the great majority, would be men who employ an assistant. As a broad generalisation, it was stated that the doctor with a big list was the subject of fewer complaints than the doctor with a small list.

Prescribing and Dispensing.

(Q. 1311.) The Acts provide that insured persons are entitled to "proper and sufficient medicines." The questions that have arisen have turned partly on whether particular substances were or were not medicines. Questions of this kind are those in which

common sense seems to meet the matter completely. No such cases under the Act have been put to formal test. The bulk of the questions that arise, however, are those under the Regulations relating to excessive prescribing. (Q. 1333.) The department has never at any time attempted to dictate to doctors what they should or should not order. The question has always been referred, in the first instance, to the local Panel Committee, and it is they who have considered as a medical question whether the things ordered in a particular case did or did not exceed what was reasonably necessary for treatment. If the doctor was not satisfied with the decision of the Insurance Committee, based on that expression of opinion by the Panel Committee, he had a right of appeal to the Ministry.

In order to reduce the number of cases arising for formal investigation, and to examine the general causes for the recent large increase in expenditure on drugs for insured persons, the Ministry has been engaged through its officers in an investigation.

(Q. 1316.) No disciplinary action, however, has been taken under the new arrangement. It has been thought more expedient to begin by a comprehensive investigation of the causes of high cost, and the regional medical officers are only employed at present in interviewing the doctors and ascertaining from them the reasons for prescribing of which the cost appears high.

Authority for the Regulations.

(Q. 1392.) The powers of the Commissioners to make regulations to check excessive prescribing were tested in the courts as early as 1915, and the regulations were held by Mr. Justice Rowlatt to be within the powers conferred on the Commissioners. The judge stated that:—

Experience shows that to carry out the Act you must have some check on extravagance, and that is what this rule was made for. In effect it says that if a doctor prescribes what is extravagant he must pay for it himself. . . . An Act of this kind ought to be construed liberally. The difficulties which emerge in the administration of an Act of this character are exceptionally great, and I ought to look at it in a practical way and construe the power with liberality. The making of this regulation, which certainly is a most beneficial one if properly administered, is well within the powers conferred by the Act.

Panel Drugs Not Inferior.

(Q. 1333.) On the question whether there was ground for the suggestion that insured persons were supplied with inferior medicines, the witnesses said there was no foundation at all for it. The department has repeatedly drawn attention to the fact that all drugs and appliances should be made available to insured persons which, on a liberal view, may be considered to be reasonably necessary for the efficient treatment of sick persons, and that full scope should be afforded for the exercise by practitioners of proper independence of judgment in the treatment of their patients. In a circular of May, 1924, the Minister deprecated any cheese-paring economy or the stereotyping of methods of prescribing, while at the same time pointing out the importance of avoiding waste and extravagance.

(Q. 1353-5.) As to stock mixtures, most Panel Committees now draw up formulæ of preparations that they believe the doctors will frequently want to supply, and which are not likely to deteriorate with keeping if made up in bulk; and chemists are encouraged to keep those ready made up in stock for reasons of economy. This has given rise to the suggestion, quite unfounded, that insured persons are less well treated than private patients. It is a practice probably adopted in every hospital in the country and by all private practitioners who do their own dispensing.

(Q. 1339-46.) With regard to the chemists, purchases have been made from time to time with test prescriptions and analyses made. This action, however, has not been as systematic and widespread as it might have been, and the department now has under consideration with the Retail Pharmacists' Union

a uniform system of investigation throughout the country.

A Limited List of Appliances.

(Q. 1312-1332.) The Acts provide that only such appliances are to be supplied as the department may prescribe by regulation. Such common appliances as spectacles, trusses, and artificial limbs are not included in the list, and the evidence goes to show that the main ground for limiting the list is the ground of cost, but also that a distinction would appear to have been drawn between things which are required in order to enable the process of medical treatment to be properly carried out and things which are required to remedy physical impairments in every-day life.

Special Arrangements for Obtaining Medical Treatment.

Very few questions were asked as to the system under which certain persons may make their own arrangements for getting treatment instead of getting it under the panel system, or as to the arrangements for getting treatment through certain approved institutions. (Q. 1375.) With regard to the first class it was stated that there was no considerable demand at the present time by insured persons to be allowed to make their own arrangements and to receive a contribution towards the cost. The main deterrent is probably the fact that the insured person may have to pay some part of his doctor's bill himself. (Q. 1379.) As to the approved institutions, it was felt that the arrangements for the investigation of complaints have not been generally satisfactory, and that some institutions have been very lax in inquiring into complaints.

Payments to Doctors.

(App. C. 125.) The Minister, after consultation with the Government Actuary, determines for each year, partly on the basis of the number of insurance stamps sold, together with any other information available, the number of insured persons in the country who would be entitled to medical benefit in that year. This number, multiplied by the agreed capitation fee, makes a central pool. The distribution of this central pool among Insurance Committees is made by the Minister after considering the recommendations of a Committee, called the Distribution Committee, set up for this purpose. The insurance practitioners are represented on this Committee. The sum allotted to each Insurance Committee area is divided locally among the doctors in such way as they themselves determine. The almost universal system is the capitation system—that is, a distribution according to the number of persons on each doctor's list. (Q. 1383.) In Manchester and Salford the distribution is on the basis of the number of services rendered, but the doctors themselves have had to devise so many checks and safeguards against the risk of unnecessary attendances that by now the result differs very little from the capitation system. It has probably survived hitherto because of the strong feeling in both those cities in favour of free choice of doctor by the patient at any time. Now that free choice at any time is allowable everywhere, it is probably only a question of time for payment by attendance to disappear both in Manchester and Salford.

The central pool for the whole country is itself based on a capitation payment as stated. (Q. 1412-14.) This has varied from 7s. a head of the insured population at the beginning, up to a maximum of 11s. in 1920, falling to 9s. 6d. in 1922, and then in 1924 to its present figure of 9s. (Q. 1388.) The witnesses were asked what was the equivalent of the 9s. expressed in terms of services rendered. They stated in reply that it was calculated that the average payment per service was about 2s. 7d. Stated otherwise, it worked out at 2s. 3d. per surgery attendance and 3s. 4½d. for each domiciliary visit. These figures, it was suggested—

would compare very favourably with the return from private practice among comparable classes, when you allow for the fact that, in the case of the insurance payment, it is a net

payment. There is no cost of collection and there are no bad debts. There is also the important difference that the doctor does not dispense for his insurance patient, whereas in industrial practice he ordinarily has to provide medicine for his private patient, and his fee in the case of the private patient, therefore, covers that as well as the attendance.

Persons Who Do Not Choose a Doctor.

The number of persons for whom the doctors collectively are paid depends, it will be seen, upon an estimate of the whole insured population made by the Government Actuary, and not on the number who actually get on to doctors' lists. (Q. 1452.) The doctors are paid for all such persons because they are at risk in respect of them, and have to give them treatment when they fall ill. For this reason no great importance is attached to the question of the actual number of such persons, which probably corresponds very closely with the number of fresh persons (about half a million) entering insurance each year. In the case of younger entrants particularly there is a tendency not to take any steps in the direction of getting on the list of a doctor until his services are needed.

Mileage Payment for Country Doctors.

(Q. 1463.) I see that the mileage grants have increased from £26,000 for England in 1913 to £250,000 in 1924, though apparently the latter figure covers Wales also. Can you indicate why such a large increase was made?—A. Because the whole basis on which mileage was calculated had to be revised. We started on the assumption that it was only necessary to make provision for areas of very special sparsity and difficulties of locomotion. . . . It was agreed at the beginning of 1920 that a mileage fund should be set up in order to pay the rural practitioner both for his expense in getting to the patient and also for the time spent in travelling over and above the time that would on the average be spent by the town doctor. The mileage fund, as from the beginning of 1920, had therefore to provide additional payments for all rural practitioners, and not only, as in 1913, for those practising in exceptionally difficult districts.

(Q. 1465.) In the distribution of the Central Mileage Fund between areas the Minister has the advice of the Distribution Committee referred to above. The distribution of the local pool is based mainly on the number of persons on the lists of the doctors who claim mileage, and their distances from those doctors, with extra provisions for areas in which there are special difficulties—for example, where a man lives in the middle of a moor and has to be reached by footpath instead of by car.

Town v. Country.

(Q. 1514-17.) Questions elicited the general view from the witnesses that the town doctor has profited more by the Insurance Acts than the country doctor. The country doctor is less well off—

partly because now he only gets the insurance capitation rate in respect of a number of people—indoor and outdoor servants of the squire, for instance—for whom before the Insurance Act he used to be paid at a pretty liberal rate. It is difficult to say how far that is due to the Act or how far the doctor is suffering from the impoverishment of the class that used to keep up big country places.

Also the country doctor is suffering from the increased mobility of the town doctor.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

FURTHER SITTINGS.

(Continued from p. 301.)

THE Commission resumed its sittings on Monday, Feb. 9th, when Mr. Montgomery Parker continued his evidence, speaking on behalf of the National Society for Lunacy Reform. He said that when patients were too poor to pay for the services of medical men from outside, the Society considered that financial assistance should be granted, perhaps annually. As to the discharge of lunatics, it was thought by his Society that the petitioner's arbitrary power to either discharge or not led to frequent abuse; sometimes members of the family shrank from the

trouble attendant on the return of the patient, and occasionally there was a fear of legal action being taken. Additional power of discharge, he insisted, should be vested in a judicial authority, without the right of veto now enjoyed by individual authorities; for licensed houses and hospitals the judicial authority should have the right of discharge. Licensed houses, Mr. Parker thought, should not be conducted with the object of making profit; some of them made larger profits than the public had any knowledge of. Their number should not be increased, and in that he was opposed to the British Medical Association. There might be a financial motive for detaining patients in these institutions. He also objected to what he termed the autocratic powers of medical superintendents of mental hospitals; he stated that long periods sometimes intervened without a patient seeing the medical superintendent at all. He agreed with the suggestion contained in a question by Lord Russell, that the appointment of a medical superintendent should not be permanent until he had occupied the post three years.

Allegations of Physical Violence.

Mr. Parker said numerous statements which his Society had received from patients did not allow of any doubt that on occasions physical violence was practised on patients. It was, he said, a feature of the age to substitute chemical violence for physical, and that was more difficult of detection. Some explanation of the use in these institutions of hyoscine was, he submitted, called for; also croton oil, the most painful and powerful purgative known. The Commission should inform itself of the purchases of croton oil over a definite period at all mental institutions. The Board of Control could demand this.

Mr. Parker was again in the witness-chair on Tuesday, when he continued his statements concerning the use of drugs in asylums, his main contention being that the disciplinary measures now usual were cruel. Environment, he said, had the greatest influence in the progress of a patient towards normal health, and so should receive close scrutiny. He alleged, in regard to treatment, that often the controlling factor was not the interest of the patient, but finance. It was a pity that the Board of Control had only recently pressed for a more extended use of open-air treatment; and there should be freer facilities for exercise. Private asylums should be required to render returns of recoveries to the Board of Control. It was not now necessary.

A further point which Mr. Parker made was that the medical staffs in these institutions must be considerably augmented. In some asylums there was practically no trained nursing staff. He pleaded also for more facilities for recreation and amusement, and the use of small libraries.

The meeting was adjourned to Feb. 24th.

NOTES FROM INDIA.

(BY AN OCCASIONAL CORRESPONDENT.)

Medical Relief in Rural Areas.

THE problem of bringing medical relief within easy reach of the rural population has been engaging the attention of the authorities for some time. The existing facilities in this respect are extremely inadequate. The great mass of the village populations have hitherto had no opportunity of coming into intimate daily touch with qualified doctors and have had to be content to a great extent with the services of unqualified men. Schemes for dealing with the difficult situation have been drafted by both the Bombay and Madras Governments. In the latter the only solution possible with the funds at present at the disposal of the Government seems to be on one of the three following alternative lines—namely, (1) the opening of a large number of Ayurvedic and Unani dispensaries, (2) the starting of a large number of itinerating or travelling dispensaries, and (3) the encouragement of

private medical practitioners (allopathic) to settle down in villages for practice by the grant of money subsidies and supply of medicines from public funds. The first alternative, though it is likely to find favour with the public, is impracticable and unrealisable at present on account of the lack of a sufficient number of duly qualified and accredited practitioners of the indigenous systems of medicine. As regards the second alternative, the starting of itinerating dispensaries has been tried on a small scale but the results have not been encouraging. The third alternative—namely, that of subsidising private practitioners who agree to settle down in villages—appears to be the cheapest and at the same time the best from many points of view. The idea is to divert to the villages the large number of unemployed medical men who now congregate in the towns for private practice. This third scheme is put forward as a practical proposition by the Government, and its working is outlined in a recent order.¹ For the present, only registered medical practitioners will be admitted to the benefits of this scheme. The subsidy to be given will be low enough to compel the medical men to exert themselves and earn the confidence of their neighbours and high enough to serve as an attraction in the initial stage until they are able to build up a practice. The grant of the subsidy will be subject to the condition that the recipients agree to settle down in specified villages and treat the necessitous poor free. They will otherwise have complete liberty to accept such fees for medical attendance and treatment as they can get. The actual working out of the scheme will be entrusted to the respective local boards; the villages will be selected by them and the medical men by their presidents. The cost of the subsidies will be met entirely by the Government and will be paid as a contribution to the local boards concerned, and they will be disbursed monthly by the presidents concerned. The subsidy of medical men in order to induce them to settle in rural areas is a somewhat novel experiment and is one of the results of which will be watched with great interest by those who believe that the real people of India are the great masses of agriculturists who never leave their fields.

King Institute of Preventive Medicine, Madras.

The report of the King Institute for 1923-24 is a document full of interest to all medical men in the Presidency, and it contains material which should attract the attention of many who are working in the tropics. In spite of the cessation of routine vaccination for four months during the hot weather, the number of cases of vaccine lymph issued rose from 2,079,915 to 2,184,590, the largest issue on record since the Institute was founded. Concurrent with this increase in issue there was a decrease of 25 per cent. in the amount of lymph unaccounted for. The new arrangements made with the Public Health Department for the distribution of lymph to vaccinators have also ensured the use of fresh lymph and effected considerable saving in the cost of packing. In their review of this part of the report the Government emphasise that success in combating the factors which combine to keep the standard of successful vaccination on a low level will hereafter depend upon the vigilance of the district health staffs.

The field of scientific research has been widely explored by Colonel J. Cunningham and his staff during the year. Interesting and important results are reported to have been achieved by research into various aspects of relapsing fever. The scheme of travelling laboratories for examination of water-supplies at railway stations in the Presidency has been dropped for the present, but the appointment of a travelling inspectorate for examination of water-supplies in the Presidency is under the consideration of Government. The question of experiments on sewage disposal plant at the Engineering College, Guindy, depends on the budget proposals for 1925-26.

¹ Government of Madras Local Self-Government Department (Public Health), Order, No. 1522, P.H., Oct. 22nd, 1924.

The staff of the Institute took a very active part in public health propaganda by preparing the material issued by the Madras Health Council for the Health and Baby Week, and by preparing and delivering lectures. In notes such as these it is difficult to give any detailed description of a report so full of excellent material, and the Government rightly congratulate Colonel Cunningham and his staff on the excellent achievements of the year and on the high standard of efficiency maintained in the Institute.

The Services.

ROYAL ARMY MEDICAL CORPS.

Cpts. to be Maj.s.: H. N. Sealy, A. Jackson (Prov.), E. C. Beddows, J. Rowe (Prov.), W. P. Croker (Prov.), A. B. H. Bridges, A. G. Brown, and R. Hemphill.

Capt. T. Parr and Lt. T. W. Davidson are secd. for duty with Sudan Defence Force.

Lt. (on prob.) M. A. Graham-Yooll resigns his commn.

TERRITORIAL ARMY.

Lt.-Col. D. J. Graham to be Bt. Col.

Maj. T. A. Hindmarsh to be Lt.-Col. and to command 50th (1st Northern) Casualty Clearing Station.

Lt. D. Ross to be Capt.

INDIAN MEDICAL SERVICE.

W. Aitchison and R. W. H. Miller to be Cpts.

D. McD. Fraser to be Lt.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flying Officers for three years on the active list: C. G. J. Nicholls and B. Pollard.

DEATHS IN THE SERVICES.

Col. Robert Isaac Dalby Hackett, C.B.E., M.A., M.D. R.U.L., died on Feb. 15th at Cheltenham in his sixty-eighth year. He was a son of W. Thomas Hackett, J.P., of Castletown, King's County, Ireland, and a younger brother of the present Dean of Limerick, the Very Rev. T. Aylmer P. Hackett D.D. Born in 1857, he was educated at Chesterfield College and Queen's University of Ireland, where he graduated M.A. and M.D., with honours. He joined the R.A.M.C. in 1881, was promoted surgeon-major in 1893, lieutenant-colonel in 1901, and colonel in 1911, retiring at the end of 1912. In 1914 he rejoined the army for the period of the late war and served to its close. Early in his army career he served in Cyprus and Egypt, and took part in the Sudan Campaign of 1885, for which he received the medal and clasp and the Khedive's Star. The following year he was transferred to Nova Scotia, but went to South Africa in 1888 to serve in the Zululand operations against Dinizulu. He was again in South Africa for the war of 1899 to 1902 as principal medical officer of the General Hospital, and was with the expedition that relieved Ladysmith, subsequently serving in later operations in Natal and Cape Colony. For these services he had the Queen's medal and clasp, and the King's medal with two clasps. After the war was over he had further periods of service at the Cape, and during 1911-12 was in India as administrative officer of the Sialkote and Abbotabad Brigades. For his services in the late war he received the C.B.E. In 1895 he married Miss Evelyn Mary Wynne-Jones, by whom he had one son and one daughter.

JOHNS HOPKINS HOSPITAL, BALTIMORE: MEMORIAL TO THE LATE SIR WILLIAM OSLER.—A large memorial plaque showing the late Sir William Osler at work in his laboratory was recently unveiled and dedicated in the medical amphitheatre of Johns Hopkins Hospital. The plaque was modelled by Dr. R. Tait Mackenzie, of Philadelphia, and was presented on behalf of a group of former associates and friends of Dr. Osler by another Philadelphia physician, Dr. Thomas McCrae. The amphitheatre was crowded to overflowing when Mrs. McCrae, a niece of Dr. Osler, unveiled the tablet. Dr. William H. Welch gave his recollections of early association with Dr. Osler in the early days of the hospital. Other speakers were Dr. Rufus Cole, director of the hospital of the Rockefeller Institute of New York, who spoke of Sir William Osler as not merely a great teacher but also "learned historian, classicist, wise counsellor and able physician," and Dr. Henry M. Hurd, who was introduced as having known Sir William Osler probably before anyone else there present. A message was sent from the meeting to Lady Osler in Oxford informing her of the memorial.

Correspondence.

"Audi alteram partem."

REX v. BATEMAN.

To the Editor of THE LANCET.

SIR,—I can only say thank you deeply for the help, moral and material, which you extended to me during my terrible period of anxiety. If I wrote pages I could not say more.

I am, Sir, yours faithfully,

New Cross-road, S.E., Feb. 16th, 1925. P. BATEMAN.

THE DIAGNOSIS OF APPENDICITIS.

To the Editor of THE LANCET.

SIR,—Every abdominal surgeon, if not indeed the profession generally, cannot but be interested in the articles which you have published on appendicitis by Mr. Rendle Short. Whilst it appears to me that there are many points upon which even Mr. Short will hardly expect agreement, the most important of these is referred to in THE LANCET of Feb. 7th by Mr. Whitehouse Parkes. The main difficulty in a minority of cases lies in the question of diagnosis. With an early diagnosis the decision for operation follows naturally, and no question of its desirability can arise when the diagnosis of appendicitis is made within 48 hours of the onset of symptoms.

Mr. Parkes's letter refers to the case of his wife, in whom the early onset of pain was absent. Judging by the records this does occur in a very small proportion of cases. Your correspondent has thus raised a very interesting point, but he has stopped short of giving us any useful clue as to its explanation. Provided that his wife had no pain 36 hours before her vomiting, the case must be placed in the category of those in whom pain as an initial symptom is completely absent. If Mr. Parkes would let us know what the anatomical position of the appendix was at the time of operation he would be increasing our knowledge of the subject and conferring a benefit on operating surgeons.

In a case of mine in whom pain was present but tenderness absent until after the appendix had perforated, it was explained by the fact that until then no part of the diseased organ had come into contact with parietal peritoneum, and hence there was no irritation of somatic nerves until after perforation had taken place. This, I think, affords one explanation of the absence of tenderness in these cases. I have never come across a patient in whom pain as an initial symptom was completely absent. The ordinary explanation of some such cases arises from the fact of there having been an interval between the generalised colicky pain and the localised pain and tenderness, and of this interval having blotted out of the patient's recollection the generalised pain which is so characteristic as the initial symptom of the disease.

Might I ask Mr. Parkes to let us know the anatomical position of the appendix, and also its pathological condition at the time of operation?

I am, Sir, yours faithfully,

Belfast, Feb. 9th, 1925. S. T. IRWIN.

To the Editor of THE LANCET.

SIR,—In his clinical lecture on the subject in your issue of Jan. 31st, Mr. Rendle Short alludes to two well-known difficulties in the diagnosis of appendicitis—namely, abdominal tuberculous adenitis and lobar pneumonia. In both of these conditions histological examination of the blood is of considerable value.

As regards the former, for the last two years or thereabouts, Mr. H. H. Greenwood, my surgical colleague at the Great Western Railway clinic,

Swindon, has sent me films from every case diagnosed as appendicitis that was not a surgical emergency. In about 20 the signs—i.e., leucopenia with relative lymphocytosis—pointed to tuberculous adenitis and operation was averted. As regards pneumonia, the degree of polynuclear leucocytosis is frequently about the same as that found in appendicitis, but in the latter condition eosinophilia is conspicuously absent, while in pneumonia it is almost always excessive.

In my view it is as essential to examine the blood in acute illness as it is to take the temperature, and it is difficult to understand why this procedure is so often omitted. No hæmatologist would claim that the blood picture should override a clinical diagnosis, but it is certainly a valuable aid in doubtful cases.

I am, Sir, yours faithfully,

A. KNYVETT GORDON, M.B.

Bedford-square, W.C., Feb. 5th, 1925.

REVACCINATION AND THE PRESENT SMALL-POX EPIDEMICS.

To the Editor of THE LANCET.

SIR,—Since last July we have had an epidemic in this institution which at first we labelled chicken-pox. Reading Dr. R. P. Garrod's lucid article in THE LANCET of Jan. 31st, entitled Para-smallpox, we found that he exactly described our cases and accordingly the Ministry of Health was communicated with. The diagnosis of small-pox was made.

While vaccinating all the resident population here we purposely included 24 cases who had suffered from the disease. Of this 24, eight reacted positively to vaccination. One of them was amongst the most severely affected and had his attack in October last. Of the remainder, three occurred in July, three in August, and one last December. All were exactly the same type of case as we have at present, and it is highly improbable that we have two different epidemics running concurrently.

It would be interesting to hear if others have had similar or diverse experiences and also to read the opinions of those qualified to give them as to the probable relation of our epidemic with small-pox proper, in view of the above facts. One of the mildest of our present cases is that of a female who has never been vaccinated in her life, and one of the worst has a vaccinia running concurrently.

I am, Sir, yours faithfully,

A. T. W. FORRESTER,

Medical Superintendent, Hatton Mental Hospital.

Feb. 14th, 1925.

THE ACIDIC VALUE OF THE URINE IN SKIN AND OTHER MANIFESTATIONS.

To the Editor of THE LANCET.

SIR,—Sabouraud, in his work on "Séborrhée, Acnés, Calvitie" (published in 1902), pointed out that the urine of seborrhœics was characterised almost constantly by *hyperacidity*, *hyperexcretion of chlorides*, and *hypoexcretion of phosphates*. He did not, however, grasp the importance of his observations; he did not apparently realise that the hyperacidity was not due to uric acid; and he was misled, like Dr. Whitfield, by the fact that on testing the urine of seborrhœics it may sometimes be found even hypoacid. And yet Sabouraud's observations might have given him the clue to the proper understanding of seborrhœa and the seborrhœic eruptions, to which he has devoted so much patient and invaluable study. I was, I believe, the first to coin the term "seborrhœic state," and, in conjunction with Dr. Semon, to insist on the value of alkalis in the treatment of seborrhœic manifestations. I hope shortly to publish fully the results of my observations since the war, but the subject is one of such great importance, not only to the dermatologist, but also to the general

physician, that, in view of Dr. Whitfield's letter, I should be obliged if you would allow me space to set forth a résumé of my conclusions.

Shortly after the war, in conversation with Dr. Whitfield, I learned that he was unable to confirm my findings, and, having a very high regard for his opinion and critical faculties, I set myself to investigate my civilian patients, with the aid of some of my colleagues. Apart from certain biochemical investigations carried out for me by Dr. Ryffel and others at Guy's, and by Dr. Broughton Alcock, I, like Dr. Whitfield, have relied chiefly on litmus paper in testing urinary acidity, and I still insist that the *alkaline tolerance* of seborrhœic patients is high, sometimes to an astounding degree. Very early in my post-war investigations I recognised the fact that when the urine of a person, even with severe seborrhœic manifestations, is first examined it may be only faintly acid, neutral, or very occasionally even alkaline, but I have found—and have verified the fact in many such cases—that when alkali is administered the urine for a time becomes progressively more acid. This apparently contradictory observation is explicable if my view of the aetiology of the seborrhœic state be accepted. To cite but one recent case—a severe acne: The patient was the son of a doctor, extremely self-conscious, and most conscientious in carrying out the treatment advised. His urine at the first examination was acid but not intensely so. He took for a fortnight never less than three doses per diem of 1 drachm of sodium bicarbonate and 30 gr. of potassium citrate, yet his urine was still strongly acid to litmus on the fifteenth day. I have had other cases in hospital, where the administration of alkali could be controlled and the urine tested daily, in which larger doses of alkali were taken over a long period without producing an alkaline urine.

Apart from the urine, I have tested the saliva (being careful to avoid the fallacy of possible acid-production from food-fermentation in the mouth) and the sweat of the palms, where, of course, there are no sebaceous glands. Having believed, since my physiological days, that the saliva was alkaline and that ptyalin was inactive in an acid medium, I was surprised to find how many people have definitely acid saliva; for the past few months I have tested this point on nearly all my private patients, and I have found that, in seborrhœic persons, the saliva usually gives an acid reaction to litmus, the acidity being sometimes as marked as that of a fairly acid urine. Some degree of the seborrhœic state is so common that many of its slighter manifestations are not considered, even by dermatologists, as abnormal, but one does meet with absolutely normal people, and it is interesting that, just as there exist seborrhœic families, so the normal non-seborrhœic state tends to have a familial incidence. My own family is a case in point. I am the youngest of six, and not one of us has ever had any seborrhœic disorders, except that I became for a while slightly seborrhœic in Mesopotamia. I have used myself and others, with no trace of seborrhœa, as controls; our saliva is always alkaline and our alkaline tolerance is low.

It was soon established by my colleagues at Guy's that the blood in seborrhœic cases showed no evidence of acidosis, but Dr. Ryffel, who has investigated a number of my patients, found that in several, usually inveterate seborrhœics the ammonia-ratio was high, sometimes strikingly so, and also the acid ratio. He also confirmed the high alkaline tolerance of some of my cases. Prof. Haldane has suggested to me that the explanation of the high alkaline tolerance, with no evidence of acidosis in the blood, might be that these persons produce a relatively insoluble acid or acids, which are with difficulty excreted by the kidney, unless the requisite quantity of alkaline bases are available, but more easily by the sebaceous and sweat glands. He advised me to try the effect of sodium phosphate, since acids are normally excreted in the urine as acid sodium

phosphate. This I did, but was not convinced that better results were obtained than with my original combination of sodium bicarbonate and potassium citrate. Recently I have prescribed a mixture of magnesium and calcium phosphate in combination with bicarbonates, but have not yet had time to draw any conclusions.

The excessive excretion of sebum (seborrhœa) and of sweat (hyperidrosis oleosa) that obtains in seborrhœic persons I believe to be due to the excretion via the sebaceous and sweat glands of acid by-products of metabolism (*not* uric acid, but probably, as some observations of Dr. Broughton Alcock would suggest, volatile fatty acids), an insufficient quantity of alkaline bases being available for their excretion via the kidneys. It is also likely that, apart from the sebaceous and sweat glands, the whole epidermis takes part in this vicarious acid excretion, and this accounts for the slight epidermal thickening, and the hypertrophy of the horny layer, with the modification of its fat-content, noted by Darier. The mucous membranes and salivary glands appear also to share in this process. It is the excretion of these acids via the skin and mucous membranes that would seem to favour the growth in them of the micro-organisms on which the complications of the seborrhœic state depend—namely, in the skin, the so-called "bottle-bacillus" (probably a yeast), the micro-bacillus of acne, which swarms in the sebaceous follicles of the seborrhœic, and various strains of staphylococci, and in the mouth and nasopharynx, streptococci and other organisms. The chronic seborrhœic is not only liable to pityriasis, seborrhœic dermatitis, acne, sycosis, boils, carbuncles, chronic blepharitis with styes, rosacea, infectious eczematoid dermatitis, miliaria rubra, and hydrosadenitis, but also to chronic nasopharyngeal catarrh, conjunctivitis, gingivitis, pyorrhœa, and balanitis.

There also may occur in the seborrhœic state a true eczema, distinct from seborrhœic dermatitis in that the inflammatory changes are not primarily due to bacterial infection, but in all probability to the actual excretion of acid by the sweat and sebaceous glands. When occurring on the palms and soles this constitutes one form of cheiropompholyx or dysidrosis. Hyperidrosis of highly acid sweat is a notable symptom. In this condition the administration of alkali in sufficient quantity is absolutely specific, and will cut short an attack without any local treatment. I do not, however, agree with Dr. Dobie that all cases of cheiropompholyx (eczematoid ringworm is, of course, excluded) are of this nature. When once an infection with micro-organisms has become established, the factors of sensitisation and specific lowered resistance to definite strains of bacteria come into play, and the administration of alkalies alone is not sufficient to cure; it is, however, a very valuable aid.

In the aetiology of the seborrhœic state, which is appallingly common, I believe the following are the chief factors responsible:—

(a) *Heredity*.—Darier, in his description of "la kérose," which corresponds clinically to my "seborrhœic state," stresses the influence of heredity. In this he is right, as it is undoubtedly a predisposing factor of importance (cp. hereditary diabetes), but, given the necessary abnormal conditions of life, the seborrhœic state may supervene even in the healthiest person. Hereditary cases, however, are much more susceptible to the influence of an unsuitable diet and a sedentary life than normal persons.

(b) *Diet and Exercise*.—The abnormal acid production that characterises the seborrhœic state is obviously an indication of deficient metabolism with the accumulation of incompletely oxidised acid by-products. A disproportion between the amount and quality of food taken and the physical energy expended is clearly, therefore, one important factor. One frequently sees the seborrhœic state develop *de novo* in trained athletes, when they abandon their games and adopt a sedentary life, without at the

same time restricting their diet. Conversely, the most confined seborrhoeic will become normal if he diets wisely and adopts a vigorous out-of-door life; the greasy skin becomes dry and clear, and the secondary infections disappear. The most important factors, then, predisposing to the development of the seborrhoeic state are an excessive dietary, particularly of soft starchy and concentrated sweet foods, an insufficient intake of alkaline salts and water, a sedentary life in over-heated, badly-aired surroundings, and lack of exercise.

(c) *Overclothing*.—The influence of overclothing is so obvious that it need not be considered. The extraordinary effect on the seborrhoeic skin of exposure of the whole body to sunlight and air can be seen by anyone who cares to visit Dr. Rollier's clinic at Leysin.

(d) *Constipation*, and dyspepsia of the fermentative type. It is useless to attempt to cure the various seborrhoeic manifestations by local treatment alone; they invariably relapse or new ones develop. The secret of success lies in the initial administration of alkalies, a physiological dietary, regular physical exercise, correction of constipation and other sources of toxæmia, and, when chronic secondary infection is present, the raising of the patient's resistance by every available means. As to the value of alkalies, which Dr. Whitfield and others deny, there is not the slightest doubt. I have kept in touch with a large number of patients, some of them medical men and students, and they find that as long as they take a sufficient quantity of alkali they keep free from active seborrhoeic manifestations. That some of them were very sceptical at the outset is sufficient to exclude an element of suggestion.

I am, Sir, yours faithfully,

H. W. BARBER.

Devonshire-place, W., Feb. 16th, 1925.

POST-OPERATIVE PULMONARY AFFECTIONS.

To the Editor of THE LANCET.

SIR.—In your report (Feb. 14th) of the discussion on the prevention and treatment of post-operative pulmonary affections, a full abstract is given of my remarks upon bronchitis, but no reference is made—probably from want of space—to the explanation which I offered of the causation of the more important complication (from the anaesthetist's point of view)—viz., pneumonia. May I be allowed to add to your report?

After stating my belief that bronchitis following abdominal operation under ether anaesthesia is chiefly due to the irritating effect of high concentrations of ether vapour, particularly in certain subjects, I proceeded to argue that there are two factors at work in the causation of surgical pneumonia—one being bronchitis, whether pre-operative or anaesthetic, or possibly due to prolonged exposure during nerve-blocking; the other being collapse, usually partial, of the lung, which as the result of this bronchitis becomes inflamed. Collapse of the lung is probably of nervous origin. That the site of operation has especial influence is proved, I held, by the very slight liability to pneumonia after non-abdominal operation, even though ether be given and the patient be bronchitic; and the fairly frequent occurrence of pneumonia after abdominal operation under a local and, occasionally, after a spinal anaesthetic—I took the view, therefore, that the selection of the anaesthetic was still an important part of the duties of the anaesthetist and that everything possible should be done to prevent the onset of bronchitis and to counteract the tendency to pulmonary stasis.

I am, Sir, yours faithfully,

FRANCIS E. SHIPWAY.

York-terrace, N.W., Feb. 14th, 1925.

TINCTURE OF IODINE (PH. FR.).

To the Editor of THE LANCET.

SIR.—In recent years many physicians in this country have been in the habit of prescribing for internal administration tincture of iodine, French Codex; from my own observations I have formed the opinion that during the last two or three years the frequency of prescribing this product is increasing. I also have a very firm conviction that when tincture of iodine, French Codex, is prescribed, the physician has in mind the tincture of iodine of the Codex 1908, which does not contain any potassium iodide, but is prepared by dissolving 10 g. of iodine in 90 g. of alcohol 95 per cent.

A preparation introduced in the first supplement of the Codex (1920) as "teinture d'iodure iodurée" contains 4 g. potassium iodide in addition to 10 g. of iodine in 136 g. of alcohol 90 per cent., and in the second supplement to the French Codex (1922) the tincture of iodine of the Codex 1908 was suppressed, and the title "official tincture of iodine" now applies to the "teinture d'iodure iodurée" of the 1920 supplement.

From these facts you will realise that when now physicians prescribe tincture of iodine, French Codex, they will not get (what I think they really intend) the tincture of the 1908 Codex, containing no potassium iodide, but the preparation containing potassium iodide which is now official. No indication of the changes appears to have been published in medical literature as far as I know.

I am, Sir, yours faithfully,

P. C. BRETT, M.B., B.S. Lond.

Queux-road, West Hampstead, Feb. 9th, 1925.

A DISCLAIMER.

To the Editor of THE LANCET.

SIR.—In view of the recent articles that have been appearing about 86, Brook-street in the *Daily News*, I feel compelled to ask you to be good enough to publish this brief note, in which I would desire to emphatically dissociate either myself or any of my colleagues with the ætiology of those articles.

I may just add that our united disapproval has found expression not only in an attempt on my part to suppress the publication of the last two articles, but also in a letter repudiating all knowledge and responsibility of them, written to the General Medical Council.—I am, Sir, yours faithfully.

DRURY PENNINGTON,

86, Brook-street, W., Feb. 16th, 1925. Medical Director.

* * * The abuses that may arise from articles signed by medical men and appearing in the lay press are obvious, and so is the good that may be done by wise and authoritative pronouncements through the same medium. Of what may lie beneath unsigned contributions there can be no definite opinion in the absence of any clue to personal bias. We publish Dr. Pennington's disclaimer with pleasure, and take the opportunity of adding that a complimentary reference to THE LANCET in a Sunday newspaper last week, crediting us with views that are only half correct, was not inspired by any member of our staff.—ED. L.

METROPOLITAN (QUEEN'S) NURSING ASSOCIATION JUBILEE.—This association, which has its headquarters at 23, Bloomsbury-square, London, W.C., will celebrate the 50 years of work it has done among the poor of central London by a service of thanksgiving to be held at the Church of St. Martin-in-the-Fields on Wednesday, March 18th, at 2.15 P.M. The association provides trained district nurses for treating the poor in their own homes, and was founded by Florence Nightingale in 1875. The association was the forerunner of Queen Victoria's Jubilee Institute to which it is now affiliated.

Public Health Services.

HOSPITAL NOTES.

THE SCOTTISH HOSPITAL INQUIRY.

THE Hospital Services Committee, appointed by the late Government to inquire into the adequacy or otherwise of the existing hospital facilities in Scotland, has now, so far at all events as at present arranged, concluded its public sittings for the taking of evidence. The Committee has held 15 sessions extending over five weeks, and has examined about 50 witnesses.

Dr. William Robertson, M.O.H. for Edinburgh, said that the general provision of hospitals for the isolation of infectious diseases was ample. As preventive medicine progressed and housing improved the demands upon isolation hospitals would probably be reduced. If real and lasting benefit was to be secured, children convalescing from measles and whooping-cough ought to be removed from the acute wards to others, where fresh-air treatment could be provided, but during acute epidemics of these infections the scarcity of beds made this impossible, and patients had to be discharged just after they had recovered from the acute stage. He held, speaking of Scotland as a whole, that the provision of institutions for the treatment of tuberculosis is unequal and that accommodation for the advanced type is insufficient. There are long waiting lists which compel premature discharge from sanatoriums. Nor is there enough hospital accommodation for the treatment of venereal diseases, more especially of the congenital form. There were no insuperable difficulties in the way of coöperation between the Voluntary, the Public Health, and the Poor-law hospitals.

Dr. G. H. Stevenson, of Glasgow, a member of the Massage Board of Scotland, claimed that by adequate organisation of massage work it might be possible to save beds in general hospitals, shorten the period of incapacity, prevent many cases of chronic invalidism and crippling, and help those already crippled. There is only one training school in Scotland, that at the Western Infirmary in Glasgow. The trained workers in other hospitals are numerically hopelessly inadequate. Nor are there any special orthopaedic hospitals on a large scale in Scotland, or comprehensive schemes for the treatment of disablements after discharge from hospitals, with the result that patients usually went back, he said, to their state on admission. A district masseuse service on the lines of the district nurse would liberate many beds and would be of more value than short periods of hospital treatment.

Dr. Alexander Shearer, a medical officer of the Scottish Board of Health, gave evidence regarding hospital and ancillary services in the Highlands and Islands, with particular reference to the application of the Highlands and Islands Medical Service Fund, which amounts to £42,000 a year. The need for specialist assistance in surgery in Highland hospitals was more urgent than the need for medical consultants, and would be even more heartily welcomed by hospital superintendents and medical practitioners generally. There was need for having at Inverness a thoroughly up-to-date hospital equipped and staffed so as to be able to provide services far beyond the boundaries of Inverness burgh. The Board had already, as an experiment, assisted in the establishment of surgeons at Lerwick, Stornoway, and Lewis. The experiment promised excellently, and it was worth considering whether it should not be extended to other areas in the Highlands, where the problem was severe. If a multiplicity of organisations were to come into being, each with its separate appeal for hospitals, ambulances, specialists, and so forth, there would be an unseemly competition for

financial and other assistance, with much waste of effort and damage to essential services. If a unifying organisation on a voluntary basis was not adopted, the inevitable alternative was the organisation of the services under a local authority as general supervisors. The general hospital accommodation in the Highlands and Islands was reasonably adequate, and in medical cases the work done was highly satisfactory; the nursing services were also adequate at present. Dentistry was one of the services which did not operate at all in the Highlands.

Mr. James Hay, Director of Aberdeen Royal Infirmary, said the voluntary system had risen to the occasion in the North of Scotland in a wonderful way. At Aberdeen Infirmary, with 320 beds, the normal waiting list was about 300; 400 beds would meet its needs. If the Health Insurance Societies were to pay even one-half of the out-of-pocket expenses the infirmary incurred on behalf of their members, £6000 would be realised. The contribution from workmen amounted last year to £3842.

THE METROPOLITAN HOSPITALS.—The deficiency in the accounts of King's College Hospital, which a year ago was £67,000, has been reduced by one-half. The King's Fund contributed £16,000 and Lord Hambleden cancelled a loan of £20,000.—Mr. A. J. H. Carlil has offered to contribute £20,000 towards the cost of establishing a Unit of Pathology at Westminster Hospital.—Princess Mary has opened extensions to the West London Hospital, which brings the number of beds up to 220, and include a badly-needed accident ward. Hitherto accident cases have had to be placed on couches. A paying wing containing 22 private rooms is among the additions.—It is hoped to enlarge the Elizabeth Garrett Anderson Hospital for Women by building a children's ward and a new maternity ward, and extending the out-patients' department at a total cost of £75,000. It is suggested that the money should be raised, in the main, by 10,000 tea-parties given by women of all classes and occupations, each guest being asked to give a donation. Such a tea-party, given by the women of the Central Telegraph Office, produced £236.—The average cost of maintaining a patient in the London Fever Hospital has fallen during the past year from £34 4s. 9d. to £24 8s. 7d.—St. Mark's Hospital is to be extended to provide better accommodation for out-patients and a larger laboratory for cancer research.

GLASGOW ROYAL INFIRMARY.—The annual report of this great hospital shows that it is suffering seriously from the increasing demands upon its resources. Nearly 14,000 in-patients and nearly 52,000 out-patients were treated during the year, the first figure being an increase of just over 1200 and the second of 3261. The receipts in 1924 reached the "record" total of £243,000. The infirmary normally accommodates 664 patients daily, but the beds occupied numbered 727. A new biochemical department is proposed. At the annual meeting Dr. James Macfarlane, chairman of the board of management, suggested, as means of relieving the pressure, the erection of an auxiliary or convalescent hospital to which many cases could be removed after short treatment in the infirmary, and the establishment of a fully-equipped nursing home or hospital for paying patients. When the new nurses' home is ready for occupation in June or July the erection of additional accommodation for out-patients will be begun. The infirmary was entirely reconstructed and the accommodation increased by 50 per cent. as recently as 1914.

QUEEN'S HOSPITAL, BIRMINGHAM.—For many years past the work of this hospital has been carried on with increasing difficulty owing to the inadequacy of the accommodation—the surgical work, for instance, is done in the same building as when the hospital was established 85 years ago. The Birmingham

Hospital Council has now approved a comprehensive scheme of enlargement, to cost £120,000. A new block behind the existing buildings will contain six new surgical wards of 20 beds each; there will be three large operating theatres with their accessories, and a large X ray department. When the surgical block has been completed a new nursing home will be provided, and other enlargements will include departments for the diseases of women, and of the ear, nose, and throat. The out-patients' and pathological departments will be entirely remodelled, and there will be a new electrical and mechanical therapeutics department. The scarcity of beds in the Birmingham hospitals is so acute that the city is said to be worse off than any other large town in the country.

ANNUAL SUBSCRIPTIONS AT LEEDS.—The effort begun last year to extend the system of annual subscriptions towards the maintenance of the four principal hospitals of Leeds is making good progress. Upon the basis of a contribution of 2s. per employee per annum 700 subscribers are giving £7000 a year. In addition, the Workpeople's Hospital Committee is collecting over £30,000 a year. To organise the extension of the system of annual subscriptions the city has been divided into 20 blocks, each with its own subcommittee which, in friendly consultation, assesses every firm separately. The waiting-list for the Leeds Hospitals is said to number 1900.

HOSPITALS IN SOMERSET.—The Somerset Voluntary Hospitals Committee has come to the conclusion, after three years' careful study of the position, that the voluntary system as hitherto worked is "not giving to the nation that full, complete, satisfactory and universal service which it needs," and that some form of co-ordinate national service is required which would preserve the valuable elements of the system. With the exception of Bath, all the hospitals are paying their way, but "the county is well able to maintain all its voluntary hospitals, provided that there be some equitable method of distributing the burden."—In addition to building the Bristol Homeopathic Hospital and providing the site at a cost exceeding £100,000, Mr. and Mrs. Melville Wills have now given £15,000 for equipment.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 7TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—small-pox, 138; scarlet fever, 1747; diphtheria, 1096; enteric fever, 25; pneumonia, 1778; puerperal fever, 51; cerebro-spinal fever, 12; acute poliomyelitis, 5; acute polio-encephalitis, 1; encephalitis lethargica, 61; dysentery, 4; ophthalmia neonatorum, 127. There were no cases of cholera, plague or typhus fever notified during the week. The number of small-pox cases showed a decrease of 18 from the number for the preceding week. Ten cases were notified from Derbyshire, 15 from Northumberland, 29 from Notts, and 71 from Yorks, North Riding (Middlesbrough C.B.).

Deaths.—In the aggregate of great towns, including London, there were 4 deaths from enteric fever, none from small-pox, 73 from measles, 17 from scarlet fever, 50 from diphtheria, 133 from whooping-cough, and 291 from influenza, as compared with 202, 195, 142, and 124 in the four preceding weeks.

In London itself the deaths from diphtheria numbered 18 and from whooping-cough 55.

OPHTHALMOLOGICAL RESEARCH IN THE U.S.A.—It is announced that a fund of \$3,000,000 (£600,000) has been raised for the establishment at Johns Hopkins University, Baltimore, of a centre for ophthalmological research. The new centre will be called the Wilmer Institute, in honour of Dr. William Holland Wilmer, of Washington, whose friends and patients subscribed half the total of the fund. The remainder was given by the General Education Board of the United States. Dr. Wilmer will assume direction of the institute. Lord Grey of Falloden, a former patient of Dr. Wilmer, is one of the contributors. In addition to laboratories, the Wilmer Institute will comprise a hospital with 60 beds, of which 40 will be for non-paying patients. It is expected that the institute will be completed by September of this year.

Obituary.

EDWARD EMANUEL KLEIN, M.D., F.R.S.

WE regret to announce the death of Dr. Klein, the famous pioneer in histological and bacteriological research, which occurred at his residence in Hove Sussex, on Feb. 9th, in his eighty-first year.

Born in 1844 at Ersec, he was educated in Vienna, and from an early age showed a marked leaning towards minute anatomy at a time when histology as a branch of science was in its infancy. At the age of 24 he reached the position of professor in the University, by which time he had published an important monograph on the arrangement of the muscles of the oesophagus, and in other ways had shown his mastery of microscopical technique. In 1871, on the invitation of Sir John Simon, then principal medical officer to the Local Government Board, he came to London to carry on some bacteriological investigations for the Board and thus gained an introduction to scientific circles in this country. During the long period in which he was associated with the Local Government Board he published in the reports of the Medical Department a series of valuable observations on numerous pathological and bacteriological subjects. At different times most of the great infective processes came under his investigation, and our knowledge of typhoid fever, epidemic diarrhoea, small-pox, and cholera have all been enlarged by his untiring researches. He reported in this way on the concurrent inoculations of different infections, on the antagonisms of microbes, on the life of pathogenic microbes in water, on protective inoculations generally and the prophylaxis of diphtheria, on oyster culture in relation to disease, on the possible association of microbes with various fevers, on the differentiation of anaerobic microbes present in the human intestine—to mention some of the general researches; while in association with Houston he reported inter alia on the bacteriological evidence of the sewage pollution of water, and on the behaviour of specific microbes in relation to cereal products. The mass of work executed for the Local Government Board during some 15 years was, it will be seen, very large, for only that with a wide range has been mentioned here, and in all of the reports his technical skill was displayed.

Shortly after joining the Local Government Board he was invited to join the staff of St. Bartholomew's Hospital Medical School, where he was first assistant lecturer on anatomy and physiology, and later director of the bacteriological department. At St. Bartholomew's Hospital he made a great reputation as a teacher, and some of our leading physicians and pathologists to-day would admit their profound debt to his instruction and personal help. He became associate editor of the *Quarterly Journal of Microscopical Science* at its outset, and in 1873 an important monograph on the anatomy of the lymphatic system appeared in that paper, which received warm notice in our columns, and sufficiently accounted to those who were unfamiliar with his work for his early election to the Royal Society. Two years later appeared his work on the lymphatic system of the lungs, in which attention was drawn to the manner in which tubercle might spread through the tissues, and about the same time he published a handbook for the physiological laboratory, in which he collaborated with Sir Lauder Brunton.

In 1879 he brought out an "Atlas of Histology" which purported to give a pictorial and literal representation of tissues of the vertebrates, and was a practical compendium of the histology of the day. The book was furnished, from preparations and specimens made by the author, with illustrations drawn and executed by the late Noble Smith, a well-known orthopaedist who was also a remarkable draughtsman. In this book Klein incorporated his previous work on the anatomy of the lymphatic system. The work was published in 13 parts, which appeared at brief intervals

and few text-books can ever have more exactly met the immediate needs of medicine than this vast Atlas. The greater portion of the illustrations and nearly the whole of the text were original, and of the latter it may be said that the form was remarkable in that the author's meaning was always perfectly clear, although his English was a comparatively recent acquisition. Five years later came the work which brought together his researches into normal histology with those into bacteriology, and his "Introduction to the Study of Specific Micro-organisms" remained for many years the classical authority on its subject. The text-book entitled "Elements of Histology" which he wrote in collaboration with Dr. J. S. Edkins also earned justly a large circulation. It went through more than one edition and was steadily revised and rewritten where necessary. The introduction given by this text-book to an understanding of the architecture and life of the individual cell, especially as regards the minute structure of the nervous system, were of the greatest educational value, especially as the text contained illustrations of the latest staining processes; in the last edition photography was introduced, when the results, if less distinct than the older semi-diagrammatic drawings, corresponded more closely with the preparations which the student had to examine for himself.

Klein's later work, such as his researches into plague and cholera, comes more readily to the mind than does his consistent labour in welding normal histology with bacteriological research. For example, he made, some 20 years ago, for the Local Government Board an elaborate study of the different methods by which rats may become infected by plague. As a result of experimental work undertaken by himself and others he was led to attribute to infected food a greater measure than had formerly been regarded as likely. He found that although fresh cultures of plague bacillus failed to induce plague when ingested by the rat, cultures which had undergone a certain amount of drying, and around which there had been formed, as it were, a protective envelope capable of resisting influences of the gastric juices, led to plague in the rodent, when after death Peyer's patches in the lower ileum were found swollen, necrosed, and packed with plague bacilli. Much of such work has remained only suggestive, and in the history of science Klein will mainly be remembered as a great cytologist.

Klein saw during his 80 years of life the rise and development of bacteriology and all which that science means to practical medicine and surgery. At the time of his birth bacteria could be described as microscopical curiosities interesting only to a few experts, while the investigation of vital phenomena under the heading of physiology was also in its early stages as far as the knowledge of to-day is concerned. Our familiarity with the structure of organisms has become infinitely larger in scope and more precise in details since his time, but it will not be forgotten that Klein was one of the first men of science to insist on the importance of studying the relation between normal cytology and bacteriology.

Dr. Klein married in 1877 Mrs. S. A. Mawley, who predeceased him, and leaves a son, Dr. Bernard Klein.

CECIL CLARKE, M.D. LOND.

By the death at Montana of Cecil Clarke, assistant physician at the Bristol General Hospital, an enthusiastic worker has been lost to the medical profession, and a man whose courage in the face of persistent ill-health was of a high order.

Clarke was born in Bristol in 1885 and was educated at Westminster and the Bristol Medical School. His clinical appointments were held at the General Hospital. While there he gained the Henry Marshall Prize, the Clarke Surgical Scholarship, and the Martyn Memorial Scholarship in 1908, and the Sanders Scholarship in 1909. He qualified M.B., B.S. Lond. in 1908, having previously obtained the Diploma

of the Conjoint Board, and having held the appointments at the institution undertook a voyage to the Far East. Later he held the appointments of resident medical officer and assistant in the pathological department at Brompton Hospital, where he had a bad attack of pleurisy, which was his first experience of the broken health which troubled him during the remainder of his life. After recovering from this illness he took up post-graduate work at University College Hospital and the London Hospital and on the outbreak of the second Balkan war joined the British Red Cross Unit which served with the Balkan army. He distinguished himself in this campaign and gained several British and Bulgarian decorations. In 1913 he took his M.R.C.P. Lond. and proceeded to Germany for further post-graduate studies. In Dresden he spent a long time in the pathological department under Prof. Schmorl; then he went to Vienna and was there when the war broke out. He hurried back to Dresden, and being unable to obtain his release he escaped through Holland, relying upon his great familiarity with the language. On his arrival in London he took a commission in the R.A.M.C. He was sent out to France to work as bacteriologist at a large military hospital dealing with civilian cases of typhoid fever. At this time there was an extensive outbreak of typhoid fever among the civil population and the refugees concentrated in the Ypres neighbourhood. Later he was transferred to Salonica, where he worked with Prof. L. S. Dudgeon and carried out some valuable researches into the morbid histology of malaria. While with the field laboratory in Macedonia he became infected with bacillary dysentery. However, he remained at his post until 1917, when he was invalided home. He then went to France again, and in spite of his ill-health insisted on taking service with a battalion. He was posted to the Sherwood Foresters and served with them through much strenuous fighting in Flanders.

In 1919 he returned to Bristol to take up the medical registrarship at the General Hospital, and a little later he was appointed assistant physician to the hospital and physician to the Queen Victoria Jubilee Convalescent Home. In 1922 his health broke down again, and lung trouble became seriously active. Throughout his long illness he adopted an entirely philosophical and professional attitude to his symptoms. His mind remained active and he wrote and read a great deal. Although he had spent such a long apprenticeship at pathological and bacteriological work he regarded this all as a preparation for clinical medicine, and it was to clinical medicine that he hoped to devote his life. His published medical papers include: a Report on a Series of Relapses in an Epidemic of Enteric Fever (*Jl. R.A.M.C.*, 1915); Search for Typhoid Carriers among 800 Convalescents (jointly), *THE LANCET*, 1916, i., 566; Cultivation of the Malarial Parasite (jointly), *ibid.*, 1917, i., 530; Investigations on Fatal Cases of Pernicious Malaria Caused by *Plasmodium falciparum* in Macedonia (jointly) (*Quar. Jl. Med.*, 1919); Congenital Disease of Pancreas with Infantilism (jointly), (*ibid.*, 1924); Renal Efficiency (*Bristol Med. Clin. Jl.*, 1922). All of these communications were stamped by the care and accuracy which were so prominent a feature of his work and character.

A friend writes of him as follows:—"To him pathology was always the foundation of medicine; medicine without pathology was unsound, and pathology without medicine, fruitless. . . . He was never known to complain about his lot, and although with his knowledge of medicine and pathology he must have been fully aware of his poor outlook, he always spoke hopefully and seemed to believe that he would become strong enough to return to some kind of medical employment."

Another writes: "Cecil Clarke was a good friend, a wise physician, a helpful colleague, and an able critic. To those who were fortunate enough to know him intimately, his friendship will always remain a treasured memory."

Dr. Clarke is survived by his widow.

J. H. MONTGOMERIE BELL, M.D., F.R.C.S. EDIN.

John Henry Montgomerie Bell, of Lowestoft, died recently at Harrogate in his forty-eighth year, after a long and painful illness patiently endured. He graduated M.B., Ch.B., at Edinburgh University in 1901, and gained the M.D. in 1907. In the same year he was admitted a Fellow of the Royal College of Surgeons of Edinburgh. He held successively the appointments of house surgeon to the Deaconess Hospital, Edinburgh, of house surgeon to the Ophthalmic Department, Edinburgh Royal Infirmary, and senior house surgeon to Rotherham Hospital. Dr. Bell was practising in Canada when war was declared, and he immediately joined the Canadian Army Medical Corps, where he gained the rank of Major. He served throughout the war, and there is little doubt that the hardships he endured when on active service had much to do with his fatal illness. Dr. Bell was an accomplished linguist and scholar.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—

The following lectures will be delivered at the College, Pall Mall East, London, on the following Tuesdays and Thursdays, at 5 o'clock. Milroy lectures: Dr. Salusbury MacNalty on Epidemic Diseases of the Central Nervous System, March 5th, 10th, 12th. Goulstonian lectures: Dr. John Alfred Ryle on the Study of Gastric Function in Health and Disease, March 17th, 19th, 24th. Lumleian lectures: Dr. Hector Cameron on Some Forms of Vomiting in Infancy, March 26th, 31st, April 2nd. Oliver-Sharpey lectures: Dr. E. D. Adrian on the Interpretation of the Electromyogram, May 5th, 7th. Croonian lectures: Dr. S. A. K. Wilson on Disorders of Motility and of Muscle Tone, with special reference to the Corpus Striatum, June 9th, 11th, 16th, 18th. Any member of the medical profession is admitted to any of the lectures on presentation of card.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Final Examination of the Conjoint Board, held from Jan. 13th to Feb. 3rd, the following candidates were approved in the subjects indicated, but are not eligible for diplomas:—

Medicine.—G. N. M. Aitkens, Charing Cross; R. G. Anderson, St. Bart.'s; R. Armsden, Univ. Coll.; H. I. C. Balfour, St. Bart.'s; C. W. Bamford and R. M. Bates, London; J. R. Beagley, St. Bart.'s; P. R. T. Becker, Guy's; Kathleen Blake, King's Coll.; W. R. Bonner-Morgan, St. Bart.'s; Margaret Bowstead, Royal Free; Elsie Boyton and J. L. Brown, King's Coll.; Eleanor G. Burdett, St. Mary's; M. F. Butler, Guy's; Mary E. Campbell, Charing Cross; A. G. Chamberlain, St. Bart.'s; R. J. K. Chattey, Middlesex; L. M. Clark, King's Coll.; D. R. T. Clendon, Univ. Coll.; Ella J. Cockram, King's Coll.; Hilda A. Cohen, Cardiff; P. V. Crameri and B. R. Crossley, Univ. Coll.; R. N. Curnow, St. Bart.'s; Evelyn J. Curtis, King's Coll.; H. E. Daniel, St. Bart.'s; A. E. de Founeska, King's Coll.; J. V. Dockray, Middlesex; J. Ewing, Leeds; Christabel S. Eyre, Charing Cross; C. R. Fielding, Manchester; Barbara Finch, Royal Free; Winifrede M. Fish, King's Coll.; W. Flowers, Leeds; F. J. T. Focnander, Middlesex; W. F. Gaisford and A. W. Gardner, St. Bart.'s; R. C. Gernond, Lausanne and London; Winifrede M. Gibson, Charing Cross; G. D. Gillbard, Middlesex; W. L. Gopsill, St. Thomas's; Sarah P. M. Griffiths, Westminster; G. S. Hale, St. Bart.'s; P. M. D. Hart, Univ. Coll.; Lynette Hemmamt, King's Coll.; J. U. Human, Guy's; L. E. Jones, St. Thomas's; W. H. M. Jones, Cardiff; P. N. Kapur, London; Frances M. Kenyon, King's Coll.; Kathleen M. Lankester, Royal Free; S. Lerner, Univ. Coll.; H. M. O. Lester, St. Thomas's; S. Levy, Middlesex; Leonora M. K. Lines, Charing Cross; D. A. Lubbock, Univ. Coll.; S. B. Malik, Charing Cross; Dorothy G. Medway, Royal Free; A. L. Moorby, King's Coll.; W. Murphy, Leeds; L. J. McGregor, St. Thomas's; C. C. Mackinnon, Middlesex and Bristol; Margaret C. Malone, King's Coll.; D. R. Martin, Guy's; J. P. Monkhouse, St. Mary's; E. W. Morgan, St. Bart.'s; Josephine W. Nagel, Royal Free; H. A. Nicholls, St. Bart.'s; Kathleen G. Norton, St. Mary's; D. Oliver, St. George's; S. G. Pandit, Bombay; Edith G. Peacock, Charing Cross; S. M. Power, London; E. P. Pratt, St. George's; Fanny Rabinowitz, Charing Cross; M. P. S. Rau, Madras and Middlesex; D. I. Rees, St. Thomas's; Nellie H. Reynolds, King's Coll.; F. E. Roberts, Birmingham; Janet M. Robertson, St. Mary's; E. A. Rucker, Middlesex; K. Samaan, Manchester; H. H. E. Schultz, St. Thomas's; G. Simon, St. Bart.'s; Constance G. Sloan, St. Mary's; Beatrice M. Smithies, Charing Cross; K. A. Soutar, St. Thomas's; A. A. Spiro, Manchester; J. M. Stirling, Charing Cross; K. R. Stokes, St. Bart.'s; Sylvia Sworn, Univ. Coll.; J. E. Swyer and

J. S. Symons, London; K. H. Tan, Middlesex; Catherine F. Taylor and Jean S. Thomson, Royal Free; F. S. Thornton, St. Thomas's; J. N. J. L. Uys, St. Thomas's; W. A. Vickers, Liverpool; Iris V. I. Ward, Royal Free; R. L. Waterfield, Guy's; Helen D. Watson and Violet M. Weston, Royal Free; W. S. Whimster, Guy's; J. D. V. Wijeyaratne, King's Coll.; D. P. Williams, Middlesex; Ada R. Winter, Univ. Coll.; and Joan Worsfold, Royal Free.

Midwifery.—N. Ahmed, Bombay and Edinburgh; R. D. Aiyar, London; C. R. Alderson, Univ. Coll.; C. B. Andree, Guy's; L. Appell, Charing Cross; G. S. Aston, Birmingham; Kathleen A. M. Ayton, Durham; J. C. H. Baird and W. A. Barnes, St. Bart.'s; Sybil K. Batley, Royal Free; W. T. E. Blackmore, London; E. Bowen-Jones, Guy's; Janet M. Breakwell and R. N. Bullock, Birmingham; F. Bunie, St. Mary's; Olive K. Burnett, Royal Free; J. T. Cahill, Middlesex and London; F. F. R. Carreck and F. Carroll, St. Mary's; R. T. Chadwick, St. Bart.'s; J. H. T. Challis, London; M. Chandra, St. George's; Eileen M. Clarke, Royal Free; Kathleen D. Clay-Beckett, Manchester; H. N. Collier, Guy's; P. V. Crameri, Univ. Coll.; K. J. J. Cursetji, Bombay and St. Bart.'s; N. Das, London; S. T. Davies, Univ. Coll.; Mirabel G. Davis, King's Coll.; Winifrede de Kok, Royal Free; G. Dietrich, St. Bart.'s; F. R. Dingle, Guy's; Dorothy Durance, Royal Free; R. P. S. Edden, St. Mary's; N. L. Edwards, Manchester; I. A. Evans, Cardiff; J. Evans, Guy's; J. Familton, Durham; W. H. Fernando, Ceylon; A. J. Foote, Sydney and London; R. A. Foucar, St. Bart.'s; E. A. Gerrard, Manchester; J. Goldberg, London; M. Gottfried, St. Mary's; A. S. Gough, Guy's; Gladys Goumont, St. Mary's; A. W. T. Green, Middlesex; Margaret K. Green, St. Mary's; H. R. Griffin, Middlesex; Sarah P. M. Griffiths, Westminster; J. L. Groom, Guy's; H. L. Gulati, Charing Cross; L. C. Gunasekara, King's Coll.; Emily M. Hall, St. Mary's; Nellie M. E. Hallinan, Charing Cross; T. S. Hanlin and Z. Hanna, Manchester; Dorothy M. Hanson, Liverpool; T. J. Hargest, Cardiff; M. J. Harker, St. Bart.'s; P. M. D. Hart, Univ. Coll.; A. R. Hill, St. Bart.'s; C. H. Ho, St. Thomas's; D. P. Holmes, Westminster; E. F. Hottinger, St. Mary's; L. E. Houghton, Guy's; G. E. Hughes and J. H. Humphris, St. Bart.'s; N. H. Ibrahim, Durham; A. O. Jacob, Madras; J. N. Jacobson, St. Thomas's; Elvy I. Johnstone, Liverpool; B. P. Jones, Manchester; R. Jones, Charing Cross; T. S. L. Jones and G. F. Kinder, Liverpool; B. Kornblum, Guy's; C. K. Lakshmanan, St. Bart.'s; Kathleen M. Lankester, Royal Free; S. Lerner, Univ. Coll.; C. A. Levy and G. L. M. McElligott, St. Thomas's; H. A. McGregor, St. Bart.'s; W. K. McKinstry, Cambridge and St. Bart.'s; A. C. Macleod and A. J. McMillan, Middlesex; Joan Malleson, Charing Cross; W. N. Maple, St. Thomas's; F. G. Martin, Charing Cross; R. C. May, Guy's; Dorothy G. Medway, Royal Free; P. B. P. Mellows, St. Bart.'s; R. H. Metcalfe, St. Thomas's; H. M. Mikhail, Univ. Coll.; A. K. Miller and N. A. Miller, St. Thomas's; Ruth L. Milne, Royal Free; D. Mitra, Charing Cross; F. E. Montague, St. Thomas's; Florence I. R. Moore, Royal Free; J. L. Morgan, St. Thomas's; W. S. Morgan, St. Bart.'s; W. Murphy, Leeds; A. N. Nanda, Dundee; Elizabeth H. R. Newbould, Royal Free; Kathleen G. Norton, St. Mary's; E. R. Owen, Liverpool; C. F. Parry and H. L. Peake, Guy's; A. P. Pearce, London; B. Perchman, Charing Cross; J. D. L. Perera, Ceylon and Sheffield; P. H. Perkins, London; R. K. Phillips, Bristol; A. Pierce, Birmingham; W. G. Platt, Leeds; C. C. Po. Guy's; E. P. Pratt, St. George's; Nellie L. Pyman, Charing Cross; M. P. S. Rau, Madras and Middlesex; T. Rees, J. L. Reeve, and D. R. Reynolds, St. Bart.'s; F. T. Ridley, Birmingham; C. E. Roberts, London; K. E. R. Robertson, St. Mary's; V. E. Robinson, Oxford and St. Bart.'s; C. J. Rozario, St. Thomas's; M. Schwartz and J. Shepherd, Univ. Coll.; D. G. Shields, St. Bart.'s; B. S. Singh, Leeds; E. G. Snallbone, Guy's; J. R. Smith, St. Bart.'s; E. F. Stead, London; Lois Stent and Mary Stirk, Manchester; S. V. Strong and A. C. Taylor, Guy's; T. H. Taylor, Leeds; G. A. J. Teasdale, Middlesex; L. Teskey, Toronto and London; D. W. R. Thomas and E. D. Thomas, Middlesex; Jean S. Thomson, Royal Free; Dorothy Tims, Charing Cross; R. S. Tooth, St. Bart.'s; Mary C. Tugman, St. Mary's; N. A. A. van Buuren, Univ. Coll.; A. B. W. van Zyl, Middlesex; J. Viljoen, Manchester; W. F. Waudby-Smith, St. Bart.'s; Iris V. I. Ward and Violet M. Weston, Royal Free; J. D. V. Wijeyaratne, King's Coll.; H. J. Williams, Birmingham; D. B. Wilson, Cambridge and Birmingham; Jessie Wiltshire, Univ. Coll.; R. M. Windeyer, St. Bart.'s; H. Winstanley, Liverpool; F. G. Winterton, St. Bart.'s; K. K. Wood, Manchester; and J. Woolf, St. Thomas's.

Surgery.—R. D. Aiyar, Madras and London; R. G. Anderson, St. Bart.'s; N. A. Arnold and H. M. H. Ashwin, Guy's; A. Ashworth, Liverpool; A. A. Atkins, London; H. M. Ayres, St. Thomas's; R. M. Bates, London; I. C. P. Beauchamp, Guy's; S. A. Belshaw, Middlesex; H. S. Bell, Liverpool; E. E. Benson, Bristol; A. T. Bettinson, St. Bart.'s; W. T. E. Blackmore, London; W. R. Blunt, St. Thomas's; N. W. Bolton, Manchester; G. M. Brooks, Birmingham; J. A. S. Brown, London; O. W. B. Browning, Univ. Coll.; H. Bruce, Leeds; Enid A. Ceiriog-Cadle, Royal Free; M. Chandra, St. George's; Gwendolen S. Chataway, St. Mary's; G. C. W. Clarke, Sheffield; Marian B. Coleman and Victoria M. Crosse, Royal Free; R. W. Cumingham, Guy's; A. J. Daly, London; G. Davies, Guy's; V. H. G. Davies, Middlesex; N. A. Dickinson and N. L. Edwards, Manchester; I. Evans, St. Thomas's; Helen E. Fergusson, Charing Cross; A. K. J. Finch, St. Mary's; A. H. W. Fleming, Manchester; F. J. T. Focnander,

Middlesex; A. J. Foote, Sydney and London; E. A. Gerrard, Manchester; R. Glasser, Liverpool; J. G. Goodman and A. S. Gough, Guy's; R. Green, St. Bart's; C. J. Grosch, Middlesex; G. T. Hankey, Guy's; C. G. Harper, Middlesex; S. Harris, St. Thomas's; J. P. Hellwell, St. Mary's; Catherine M. Hext, London; C. H. Highfield, Guy's; J. D. Hindley-Smith, St. George's; G. S. Hirst, Leeds; R. St. J. Honner, Sydney and Middlesex; W. Hughes, Middlesex; D. Imber and F. F. Inianitoff, St. Bart's; S. W. Innes-Smith, Sheffield; J. N. Jacobson, St. Thomas's; I. H. Jones, Charing Cross; T. S. L. Jones, Liverpool; G. W. Keele, Univ. Coll.; R. St. J. Kemm, Bristol; H. Kessel, Guy's; G. M. King, King's Coll.; O. F. A. Krause, Guy's; D. F. Lawson, St. Thomas's; W. E. Lishman, Liverpool; J. B. Lloyd, St. Bart's; T. J. Lloyd, Cardiff; Aileen I. McMahon, Charing Cross; D. H. Macleod, Middlesex; C. H. Mason, St. Mary's; J. A. A. Meckelburg, Guy's; A. K. Miller and N. A. Miller, St. Thomas's; V. S. Mitcheson, Cambridge and Birmingham; S. K. Montgomery, Univ. Coll.; Florence I. R. Moore, Royal Free; H. Moore, Guy's; W. G. R. Morris, Bristol; Marjorie Murrell and Elizabeth H. R. Newbould, Royal Free; B. V. O'Connor, Middlesex; W. Ogden, St. Bart's; Gwynedd M. E. Olive, Royal Free; R. W. L. Pearson, Liverpool; K. R. T. Peiris, King's Coll.; R. A. M. Pennington, Liverpool; S. M. Power, London; A. B. Plant, Guy's; T. B. Prys-Jones, Middlesex; P. E. Pym and W. E. H. Quennell, St. Bart's; J. Raisman, Leeds; R. J. Rankin, Cardiff; J. R. Ratcliffe, Guy's; E. W. Riches, Middlesex; A. W. Riddolls, Guy's; T. W. E. Royden, St. Bart's; C. J. Rozario, St. Thomas's; H. J. Selby, Guy's; S. Q. Servante, Middlesex; C. F. J. Smith, St. Mary's; J. R. Smith, Cambridge and St. Bart's; R. K. Smith and J. S. Spickett, St. Bart's; G. H. Steele, Univ. Coll.; Lois Stent, Manchester; Catherine E. Stephen, Univ. Coll.; W. K. Targett, Guy's; J. L. Thomas, Middlesex; O. C. Tobin, London; H. Trafford, Guy's; K. A. Turner, Leeds; L. G. W. Ulrich and A. B. W. van Zyl, Middlesex; J. Viljoen, Manchester; T. E. Walsh, St. Thomas's; E. C. Warner, Guy's; Helen D. Watson, Royal Free; R. A. K. Wiener, St. Thomas's; E. C. P. Williams, Middlesex; H. G. Wimbush, Guy's; R. M. Windeyer, St. Bart's; K. K. Wood, Manchester; H. M. Woodman, King's Coll.; and E. W. C. Wouterz, St. Mary's.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council of the Royal College of Surgeons held on Feb. 12th, Sir John Bland-Sutton, President, in the chair, Mr. Arthur Percy Dodds-Parker, surgeon to Radcliffe Infirmary, Oxford, was elected a member of the Court of Examiners in Surgery in the vacancy caused by the retirement of Mr. John Murray, surgeon to Middlesex Hospital. Mr. James Sherren was appointed Bradshaw Lecturer, and Prof. William Wright, F.R.S., was appointed Thomas Vicary Lecturer for the ensuing year.—The best thanks of the Council were given to Mr. H. H. Hope-Pinker for his presentation of the plaster model of his bust of the late Sir George M. Humphry.—The President reported that a meeting of Fellows would be held at the College on Thursday, July 2nd, at 2.30 P.M., for the election of three Fellows into the Council in the vacancies occasioned by the retirement in rotation of Mr. V. Warren Low, Mr. James Sherren, and Sir John Lynn-Thomas; that notice of the meeting would be given to the Fellows by advertisement and by circular on March 6th; that March 16th would be the last day for the nomination of candidates; and that a voting paper would be sent on March 31st to every Fellow of the College whose address is registered at the College.

Diplomas of Member were conferred upon 208 candidates who have passed the requisite examinations and have complied with the by-laws. The following are the names and medical schools of the successful candidates:—

M. Abse, Cardiff and Univ. Coll.; J. D. Allen, Cape and St. Bart's; G. T. Allerton, London; C. A. Amesur, St. Thomas's; Kathleen J. Atkinson, King's Coll.; Margaret A. Bannerman, Royal Free; W. D. Beck, Birmingham; C. E. G. Beveridge, Oxford and St. Bart's; O. P. Bewers, St. George's; Anna M. V. Bonhote, King's Coll.; V. H. Boobyer, St. Mary's; W. A. Bourne, Cambridge and St. Bart's; R. N. Brandwood, Guy's; S. Brest, H. F. Brewer, D. A. Brigg and D. J. Brims, St. Bart's; R. J. Brocklehurst, Oxford and St. Bart's; T. H. P. Brooks, London; Margaret H. Brown, Charing Cross; W. A. Browne, Madras and St. Mary's; Olive B. Buckley, King's Coll.; W. H. Cameron, Toronto and Middlesex; A. F. Chalkley, Leeds; Gwendoline Chave, Royal Free and St. Mary's; H. F. Chillingworth, St. Bart's; G. F. Chissell, Middlesex; L. Chodorsky, St. George's; J. Chronnell, Manchester; H. A. Clegg, Cambridge and St. Bart's; A. V. Clemmey, Oxford and Guy's; Doris M. Collins, Royal Free; L. N. R. Comty, London; L. C. Cook, Cambridge and St. Thomas's; W. H. M. Cowper, Middlesex; G. P. Craggs, Durham and St. Bart's; Dorothy E. Crellin, Bristol; J. Currie, St. Bart's; M. Cutner, St. Mary's; Gweneth M. Daniel and Annie E. C. Davies, Westminster; A. L. Davies, Oxford and St. Thomas's; J. R. Davies, St. Thomas's; W. H. Davies, Westminster; A. R. Davison, Cape and St. Thomas's; M. S. Dawhurst, Cambridge and Univ. Coll.; Charlotte D. N. de Wilde, Royal Free and London; G. E. Ellis, St. Bart's; O. M. Ellis, Cardiff; C. W. Evans, Univ. Coll.; J. Evans, Cardiff and Charing Cross; N. B. Farman, Charing Cross; J. T. Fathi, London; L. Fatti and C. F. Fernandez, Univ. Coll.; M. G. Fitzgerald, Cambridge and

St. Bart's; Dorothea C. Forbes, Royal Free and St. Mary's; G. R. Ford, Guy's; W. S. Fricker, Cardiff and King's Coll.; T. M. Frupp, Guy's; O. P. Giles, Birmingham; G. D. Gordon, Cambridge and St. Thomas's; H. W. Gordon, Cambridge and St. George's; R. A. Grant, Guy's; F. N. Green, Cambridge and Liverpool; A. L. Greenway, Calcutta and King's Coll.; D. L. Greig, Middlesex; J. M. Hall, King's Coll.; Constance I. Ham, Bristol; G. Hamada, Birmingham; J. E. S. Hamilton, Bristol; C. H. Hampshire, Univ. Coll.; A. W. Hanlon, Liverpool; Hans Raj, King's Coll.; Irene D. F. C. Hastlow, Birmingham; N. H. R. Hatfield, Cambridge and St. Mary's; C. W. Healey, Liverpool; S. Melberg, Zurich and London; A. Helmi, Cairo and St. Thomas's; Freda K. Herbert, King's Coll.; E. Herzberg, Heidelberg and Univ. Coll.; A. E. Hill, Guy's; C. H. Hilliard, Cambridge and St. George's; Minnie E. Hope, Royal Free; E. C. Hudson and D. B. Hughes, London; Katharine E. W. Hulse, Charing Cross; O. R. Humphreys, Cardiff and London; F. S. Hunter, Birmingham, Guy's, and Bristol; O. L. Hutchinson, St. Andrews and London; Joy Hwa, Birmingham; S. Hyman, Leeds; Elizabeth Jacobs, St. Mary's; Kate D. James, Royal Free and St. Mary's; E. J. Jenkins, Birmingham; C. W. W. Jeremiah, Cardiff and Middlesex; D. F. Johnstone, Ceylon and King's Coll.; L. A. Key, Cambridge and St. Thomas's; Caroline B. Kibble, Royal Free; C. T. Kitching, Cape and St. Thomas's; W. R. Kusel, St. Thomas's; Marjorie A. M. Lambert, Royal Free; G. S. Landon, Guy's; M. C. Lavin, London; H. Levy, Cape and St. Bart's; H. Lewis, Guy's; A. C. Liesching, St. Bart's; L. A. N. Line, Birmingham; W. H. G. M. Ling, Edinburgh and St. Mary's; Madeline R. Lockwood, Univ. Coll.; A. C. Lysaght, Bristol and Guy's; Catherine B. McArthur, Roy. Free; S. McClements, King's Coll.; F. G. Macdonald, St. Thomas's; Dorothy F. McIntosh, Charing Cross; J. H. Macpherson, King's Coll.; Helena M. J. McQuaid, St. Mary's; R. G. Malphaut, Univ. Coll.; J. P. Marsden, Cambridge and St. Thomas's; G. R. Marshall, St. Mary's; E. L. Martin, Charing Cross; A. W. C. Mellor, Cambridge and St. Bart's; C. P. Miller, St. George's; F. C. Miller, Guy's; G. J. Morris, Cardiff and Middlesex; C. F. Morrison, Guy's; A. M. Murray, Middlesex; W. R. Nash, Cardiff and St. Bart's; Margaret I. Neal, London; E. L. Newell, Oxford and St. Thomas's; R. A. Newsom, King's Coll.; H. W. Nicholson, Cambridge and St. Thomas's; J. A. Noot, Cardiff; R. A. Norman and J. N. D. O'Rafferty, Guy's; J. V. O'Sullivan, Galway and London; Evelyn D. Owen, Cardiff and Charing Cross; G. W. C. Parker, Cardiff and St. Bart's; A. E. Parkes, St. Bart's; W. Parry-Jones, London; R. Paton, Cardiff and Middlesex; V. Patrick, Manchester; F. L. Patterson, London; Gladys L. Pearson, Royal Free; A. D. Pegg, St. Thomas's; Gwyneth M. Pennant, Cardiff and King's Coll.; H. C. Pierce, Cambridge and Liverpool; C. P. Pinckney, Cambridge and St. George's; L. W. Proger, Middlesex; D. C. Prowse, Bristol; R. S. Pyrah, Leeds; V. I. Raman, Madras and London; C. Rankin, Liverpool; M. D. Rawkins, St. Bart's; J. T. Rees, Cardiff; Olwen M. Richards, Cardiff and Charing Cross; J. T. C. Roberts, Liverpool; J. J. R. Robinson, St. Thomas's; Wemyss C. Robinson, King's Coll.; G. F. Rowbotham, Manchester; Alysoun H. Rowntree, Royal Free; A. B. Rufail, Cairo and King's Coll.; K. G. W. Saunders, St. Thomas's; S. D. Schultz, Manitoba and Middlesex; C. E. Sharp, McGill and Univ. Coll.; T. A. Shaw, Guy's; Frances E. Smith, Charing Cross; S. M. T. Smith, Bristol; A. D. Soares, Bombay; K. H. Southall, Univ. Coll.; I. P. Spurrell, Guy's; Ethel L. A. Stamborg, Royal Free; B. G. Staniland, London; R. O. Stern, Charing Cross; D. D. S. Stewart, King's Coll.; P. Subbaramayya, Madras and London; A. F. Taylor, St. Bart's; E. J. Thomas, Cardiff and St. Thomas's; J. D. S. Thomas, Guy's; W. S. Thomas, Univ. Coll.; E. Thompson, St. Thomas's; W. R. Thrower, St. Bart's; T. G. Tresidder, Guy's; E. A. Trim, Cambridge and St. Thomas's; V. C. Tughan, Univ. Coll.; Beatrice M. Upshohn, Madras and Royal Free; L. C. D. van der Borgh, Ghent and Univ. Coll.; H. Van der Post, Guy's; G. B. W. Walker, Cambridge and St. Mary's; R. A. Walsh and L. B. Ward, St. Bart's; Catherine Waterson, Univ. Coll.; H. V. Wells, Charing Cross; J. Whillis, Durham; F. L. White, London; C. R. Williams, Leeds and London; D. G. Williams, Cardiff and King's Coll.; E. R. Williams, Cardiff; H. H. Williams, Liverpool; D. A. Wilson, Middlesex; Emily A. C. Wilson, Charing Cross; H. M. Worth and C. L. Worthington, Guy's; Annie Yoffa, Cornell and Royal Free; G. C. Young, St. George's; and J. C. Young, Guy's.

The diploma of Fellow was also conferred upon Frederick H. Scotson, Manchester University and St. Bartholomew's Hospital, and Clement Sturton, Cambridge University and St. Bartholomew's Hospital, who have previously passed the requisite examinations and have now attained the age of 25 years.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE: APPOINTMENT OF RHODESIAN RESEARCH FELLOW.—In connexion with the arrangements recently entered into by the London School of Hygiene and Tropical Medicine with the Government of Southern Rhodesia for the development of research work in that country, the London School has appointed for a term of three years Dr. G. R. Ross, M.B., Ch.B., D.P.H., Ph.D., to be Rhodesian Research Fellow.

UNIVERSITY OF LONDON.—A lecture entitled the Relation of Paralysis Agitans to the Parkinsonian Syndrome of Epidemic Encephalitis will be given in the Lecture Hall of the Royal Society of Medicine, 1, Wimpole-street, W., by Prof. R. Cruchet, professor of pathology and general therapeutics in the University of Bordeaux, at 5 P.M., on Wednesday, Feb. 25th. The chair will be taken by Sir Humphry Rolleston. The lecture, which will be delivered in English and illustrated with lantern slides, is addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

Three lectures on the History of Medicine will be delivered at University College Hospital Medical School by Dr. Charles Singer, on Thursdays, March 5th, 12th, and 19th, at 4.15 P.M. The subjects of the lectures are: (1) History of Influenza; (2) History of Diphtheria; (3) History of Typhoid Fever. The lectures are open to all medical students of the University of London.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Special attention is directed to the informal discussion on post-graduate study, open to all members of the medical profession in London, including, of course, Members of the Fellowship of Medicine from the Provinces and Overseas, on March 18th, at 6 P.M., at 1, Wimpole-street, London, W.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The seventeenth meeting of the Commission was held at the Home Office, Whitehall, on Feb. 12th, Lord Lawrence of Kingsgate in the chair. Mr. C. H. Waring, representing the group of Catholic Approved Societies, gave evidence on questions of additional benefits and insurance of married women. Thereafter the examination of Mr. F. W. Daniels, chairman, and Mr. P. Rockliff, secretary of the Joint Committee of Approved Societies, was continued and concluded. The National Insurance Beneficent Society, represented by Mr. G. W. Canter and Mr. Rockliff, was then heard on the question of its administration of treatment benefits. Proof copies of the oral evidence and the relative statement submitted at the meeting of Jan. 29th, are now on sale at H.M. Stationery Office (2s. 3d.).

HUNTERIAN SOCIETY: ANNUAL DINNER.—The annual dinner of this society was held on Feb. 12th at the Hotel Victoria, London. Mr. W. H. Carson, the President, was in the chair, and about 150 Fellows and their guests were present. "The Memory of John Hunter" was proposed by the President, and Sir Francis Newbolt gave the toast of "The Hunterian Society," to which the President responded. Sir Bruce Bruce-Porter paid a tribute to the Lord Mayor and the Corporation of London, and the Lord Mayor replied. The toast of "The Guests and Sister Societies" was proposed by Dr. W. Langdon Brown, and was acknowledged by Lord Carson, the Lord Bishop of London, and Sir St. Clair Thomson. Dr. Ernest Young proposed "The Chairman." During the evening a pleasant programme of songs was given by Mr. A. Rosenörn-Lamg, accompanied by Miss Marion Farr.

PUBLIC HEALTH ADMINISTRATION IN LIVERPOOL.—At a meeting of the Liverpool Medical Institution on Feb. 12th Dr. E. W. Hope gave a sketch of the sanitary advances of Liverpool, and of the measures taken to ameliorate the conditions resulting from the singularly rapid growth of the city at a time when sanitation was very imperfectly understood and when no legislative powers existed to check or remove the rapidly growing evils. Much of the earlier local legislation had formed the basis of the Public Health Acts of the country, but the sanitary necessities of Liverpool had made necessary many applications to Parliament. The great housing operations, both within the city and in its outskirts, were illustrated, as well as the measures which led to the present unstinted water-supply; transported from the purest sources 60 miles away, it was now, he said, available for delivery to every floor in every house at the moderate cost of 1½d. a ton. The measures which lead to the establishment of the present efficient hospital and sanatorium system were traced, and it was pointed out that the term "Infectious Hospital," as applied to properly spaced institutions upon an area of some 200 acres, was of very different significance to the term as applied to hospitals of half a century ago. An account was also given of the development of the individual and as well as the environment. Hygiene, uses of health visitors, antenatal and postnatal centres, maternity homes, infant welfare centres, control of food-supplies, and other important accessories were dealt with. It was with a view to making sanitary problems intelligible and interesting to the general public that the University School of Hygiene was established.

The sum raised on Poppy Day, 1924 (Earl Haig's Appeal for Ex-Service Men of all Ranks), was, up to the end of December last, £314,598.

SOCIETY OF M.O.H.'s: MATERNITY AND CHILD WELFARE GROUP.—Attention is drawn to the date and time of the meeting of this society, as announced in our Medical Diary of this week. The customary date and time of these meetings have been changed in the hope that the new arrangement will prove more convenient to the members.

DONATIONS AND BEQUESTS.—By the will of the late Dr. Herbert Williamson, of Queen Anne-street, Cavendish-square, W., the testator left £1000 to the endowment fund of the Medical College of St. Bartholomew's Hospital; and £200, his medical books, and surgical instruments to his colleague, Dr. John Davis Barris.

PUBLIC HEALTH (PRESERVATIVES, &c., IN FOOD) REGULATIONS, 1925.—The Minister of Health has caused draft Regulations to be prepared to give effect to the principal recommendations of the recent Departmental Committee on the Use of Preservatives and Colouring Matters in Food. Copies of the draft Regulations entitled "Draft, dated Feb. 17th, 1925, of the Public Health (Preservatives, &c., in Food) Regulations, 1925, proposed to be made by the Minister of Health" may be purchased directly or through any bookseller from H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Any representations on the draft Regulations should be sent to the Secretary to the Ministry within a period of 40 days from this date. The Regulations to be made by the Minister of Health will apply in England and Wales. Regulations in similar terms applying to Scotland will be made by the Scottish Board of Health. Copies of the draft of these Regulations may be purchased from H.M. Stationery Office, 120, George-street, Edinburgh.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee 20 cases were considered and £378 voted to 16 applicants. The following is a summary of some of the cases relieved:—

Widow, aged 47, L.M.S.S.A. Lond. who practised in Wales and died in 1921. Since husband's death applicant has tried to support herself and children by keeping a boarding house, but this failed, and she is likely to obtain a post as music mistress in a school on the South Coast when she can have her small daughter, aged 4, with her. Applicant asks for £12 to cover three weeks' board and lodging in London, fares for self and child to settle up her affairs in the Midlands before taking the post. Voted £20.

Widow, aged 37, of M.B. Glasg. who practised in Lancashire and died in 1922. Applicant is left with three children, aged 10, 8, 6½. Her total income is 30s. a week and she has been only able to earn very little by needlework. The small house they live in is too small to let in any way. Applicant was in hospital during the autumn to undergo an operation. Has run into debt, and school fees are owing for autumn term. Voted £5 and £20 in four instalments.

Widow, aged 87, of M.R.C.S. Eng. who practised in Bristol and died in 1885. Applicant is bedridden and has now to have a nurse to look after her at night as the daughter, aged 57, is only able to do so during the day. Applicant's total income is £100 and the rent is £39 per annum. Circumstances do not permit sufficient food at times and very little firing, as there is not enough money to buy coal. Voted £5 and £26 in four instalments.

Widow, aged 71, of L.R.C.P. Edin. who practised in London and died in 1918. Applicant has cataract and she is only able to do a little knitting by which she earned £3. Her youngest daughter has to look after her mother and she is only able to do a little spinning. The applicant's income is £84 a year from property and the daughter's £10. Rent 12s. a week for three rooms. Voted £18 in 12 instalments.

Daughter, aged 41, of M.B. Edin. who practised in Australia and died in 1883. Applicant is a trained singer and until she was taken ill earned quite a good income as a singer. The Fund have helped her mother from time to time and who now has an Epsom Pension. As applicant is suffering from chest trouble the doctor has ordered her to Switzerland and she is asking the Fund to help her with her expenses out there. Voted £20.

M.R.C.S. Eng., 1893, aged 53. Dependent on locomotens work entirely. Nearly two years resident in hospital for abscess of rectum. Brothers and sisters allowed him 12s. a week while in hospital. Brother is unable to keep applicant, and a small fund raised for him enables applicant to pay his brother £1 for board and lodging. Applicant asks for grant to buy dressings and to pay for colotomy belt and travelling expenses to and from hospital. Voted £5 and £26 in 12 instalments.

Daughters, aged 79 and 78, of L.A.H., 1836 who practised in London and died when applicants were quite young. The two sisters lived in a free cottage for 14 years and their income amounted to £66 a year each, including the Old Age Pension. The youngest one suffers from loss of memory and the elder from Bright's disease and paresis of both legs. These ladies have had to be removed to the Cottage Hospital at a cost of 2 guineas a week. Voted £26 in 12 instalments each.

Subscriptions may be sent to the Hon. Treasurer, Sir Charters Symonds, K.B.E., M.S., at 11, Chandos-street, Cavendish-square, London, W.1.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

New Bills Presented.

THE following new private Members' Bills were introduced and read a first time in the House of Commons on Friday, Feb. 13th: Lieut.-Col. Lambert Ward: A Bill to provide for the permanent adoption of Summer time. Sir Geoffrey Butler: A Bill to make further provision for the adoption of Children by suitable persons. Mr. Rennie Smith: A Bill to provide for the abolition of capital punishment and to substitute other punishments therefor. Mr. Womersley: A Bill to amend the Public Health Acts 1875 to 1907 and the Baths and Washhouses Acts 1846 to 1899 in respect of matters for which provision is commonly made in local Acts and for other purposes relating to the public health. Mr. Young: A Bill to amend the Blind Persons Act 1920. Major George Davies: A Bill to amend the Sale of Food and Drugs Act 1875 by regulating the liability of milk sellers in respect of milk adulteration. Capt. Bowyer: A Bill to amend the Bastardy Laws.

The following Government measures were also introduced and read a first time: Sir W. Joynson-Hicks (Home Secretary): A Bill to amend the law with respect to guardianship and marriage of infants: Sir J. Gilmour (Secretary for Scotland): A Bill to extend further the duration of the Poor Law Emergency Provisions (Scotland) Act 1921 and to amend certain provisions of that Act as amended by the Local Authorities (Emergency Provisions) Act 1923 and the Poor Law Emergency Provisions Continuance (Scotland) Act 1924; and Bill to authorise local authorities under the Public Health (Scotland) Act 1897 to make arrangements for providing medicines and treatment to persons suffering from diabetes.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 11TH.

Progress in Housing.

MR. TREVELYAN THOMSON asked the Minister of Health the number of houses at present in course of construction under the various State-assisted schemes and the number under construction in February last.—Sir KINGSLEY WOOD (Parliamentary Secretary for Ministry of Health) replied: Particulars are not yet available as to the number of houses in course of construction on February last, but the following table shows the position on Jan. 1st, 1924 and 1925:—

Scheme.	Jan. 1st.	
	1924.	1925.
Housing, Town Planning, &c., Act, 1919	4,873	1,658
Housing, &c., Act, 1923	14,102	49,196
Housing (Financial Provisions) Act, 1924	—	3,173
Totals	18,975	54,027

New Factory Legislation.

MR. RAINE asked the Home Secretary whether it was the intention of the Government to introduce a Bill to consolidate the enactments relating to factories during the present Session: and, if so, whether the Bill would differ materially from the Bill introduced for that purpose in the last Session of Parliament.—Sir WILLIAM JOYNSON-HICKS replied: It is hoped, as announced in the King's Speech, to introduce a Bill this Session to amend and consolidate the Factory and Workshop Acts, but I am not in a position to make any statement as to the provisions of the Bill, which have not yet been settled.

THURSDAY, FEB. 12TH.

Experimental Houses.

The House went into Committee of Supply on a Supplementary vote of £10 for the Salaries and Expenses of the Ministry of Health, including grants and other expenses in connection with housing, Capt. FITZROY in the chair.

Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) referred to the grant towards the cost of demonstration houses. He said that so far as arrangements had already been made it was proposed that the local authorities should erect three kinds of specimen houses—first, the Weir house made by G. & J. Weir, Ltd., of Glasgow; secondly, the Telford type of house made by Messrs. Braithwaite & Co., of West Bromwich, and thirdly, the type made by Messrs. James Wild & Co., of Manchester. These tests were being made as a result of the recommendation of the expert committee presided over by Sir Ernest Moir and set up by the late Minister of Health. That report contained the signature of George Hicks, General Secretary of the Amalgamated Building Trade Workers. The cost to the local authorities in relation to these experiments had been

fixed at a flat price. The price of the Weir houses to each local authority was £400, the authority themselves providing the foundations, paths, drainage roads, &c.; the price of the Telford house was £150, the local authority providing the foundations, &c., outside the concrete foundations. The price of the Wild house had yet to be fixed. The Minister of Health was to contribute to the cost of these experimental Weir houses the sum of £200, the "all in" cost being about £525. None of these experimental houses would come under the special contributions laid down in the 1924 Housing Act. In a very short time now 25 local authorities up and down the country would be erecting these houses, which were regarded by the Minister of Health as a temporary and valuable contribution to the housing problem. At the present there were some 199,000 houses authorised, of which 52,000 were completed at the beginning of the year. That left 150,000 authorised houses to be built. These would take, looking at the matter in the most favourable light, until the autumn of 1926 to complete. Under these circumstances very few people would say that these experiments ought not to be made.

MR. A. GREENWOOD (who was Parliamentary Secretary to the Ministry of Health in the Labour Government) complained that the Government had been too precipitate in giving an advertisement to the Weir type of house over other types.

MR. VIANI, another Labour Member, said that the steel house could never be vermin proof, and the result of their erection would be that there would speedily be more slum areas than existed at present.

LT.-COL. FREMANTLE said that if those who criticised the proposed experiments in new methods of house construction had had the control of scientific research in the last 50 years there would have been no progress in medical science. It was because researchers, whether in science or practical life, were prepared to take risks that they were able to get an advance. He agreed with many of the critics of steel houses that on the face of them they were not likely to be a permanent solution of the housing problem. In his experience both as a medical officer and on the London County Council he had been face to face with experiments of almost every kind and the result almost always was that he, like the Persian philosopher, "Came out by the same door as in I went." But they must go on with the experiments. The steel house was only one experiment out of many, but it was one which on the face of it must stand as offering a golden opportunity for meeting the present housing need.

The debate was adjourned till the following day when the vote was agreed to without a division.

Ex-Service Men in Mental Hospitals.

COL. SIR ARTHUR HOLBROOK asked the Minister of Pensions, whether his attention had been called to the fact that the London County Council were contemplating proceedings to enforce payment by boards of guardians who had refused payment hitherto for the maintenance in mental hospitals of ex-Service patients who had become chargeable to the boards; and whether he would consider taking such steps as might be necessary to ensure that ex-Service patients mentally affected as the result of service in the war should be maintained at the expense of the nation.—Major G. C. TRYON replied: The cost of maintenance in Mental Hospitals of ex-Service Men, whose condition was caused by their war service, is, and always has been, borne by my Department. If, however, as I gather the cases which my hon. and gallant friend has in mind, are certain cases in which the men's unfortunate condition has been ascertained not to be due in any way to war service, the suggestion made is not one that concerns my Department.

Medical Men and Overseas Military Service.

Sir ARTHUR HOLBROOK asked the Minister of Pensions whether he would consider the desirability of conceding the principle that temporary full-time medical men in the service of the Ministry of Pensions who served overseas during the late war, and especially if they were invalided or disabled in consequence of their service, should be retained when it was found necessary to reduce the numbers serving, in preference to those temporary full-time medical men who did not serve overseas.—Major G. C. TRYON replied: The chief considerations in determining the continued employment of medical officers in the Ministry of Pensions are efficiency and the possession of the necessary qualifications for the duties required to be performed. Subject to those considerations, preference is given to an officer with overseas service, more especially if he has a war disability, over one with home service only.

Polycythæmia and Workmen's Compensation.

Colonel WEDGWOOD asked the Home Secretary whether the occurrence of the comparatively rare disease of polycythæmia in direct connection with workers in ammonium sulphate production constituted this disease an industrial disease; and, if so, would he have the disease scheduled as

such under the Workmen's Compensation Act, 1906, so that these very painful cases could receive some compensation.—Sir W. JOYNSON-HICKS replied: I have only heard of one case of this disease the cause of which is obscure, and there is no information at present before me which would justify its being classed as an industrial disease.

Child Adoption.

Lieut.-Col. HEADLAM asked the Secretary of State for the Home Department whether the Departmental Committee on Child Adoption, presided over by Mr. Justice Tomlin, had presented a report; and, if not, when such Report might be expected.—Sir W. JOYNSON-HICKS replied: The Committee has not yet presented a report and I am unable to say when the Report may be expected. I understand that the committee has not yet finished taking evidence.

Legitimacy Bill.

Capt. BOWYER asked the Prime Minister whether he would introduce as soon as possible the Legitimacy Bill.—Sir W. JOYNSON-HICKS (Home Secretary) replied: I hope that it may be possible to introduce this Bill in another place at an early date.

Dwelling-Houses Used as Factories.

Capt. GARRO-JONES asked the Minister of Health what steps he proposed to take to meet the representations of local authorities in London urging the passage of a Bill to prevent the user of dwelling-houses as factories or workshops.—Mr. NEVILLE CHAMBERLAIN replied: I have had under consideration the representations referred to. One effect of the Rent Restriction Acts is that conversions of this kind are strictly limited. It would appear, therefore, that the matter is not of urgency, but I should be prepared to look into it further on receipt of evidence to the contrary.

Preservatives in Food.

Capt. GARRO-JONES asked the Minister of Health whether in view of the widespread support which the Report of the Departmental Committee on the use of preservatives and colouring matter in food had received, and in view of the specific nature of the committee's conclusions, he could tell the House if he would introduce legislation at an early date to give effect to those conclusions.—Mr. NEVILLE CHAMBERLAIN replied: I am proposing to publish at an early date draft regulations designed to give effect to the majority of the committee's recommendations which, I am advised, can be carried out without legislation.

Unemployment Benefit for Small-pox Patients.

Miss WILKINSON asked the Minister of Labour whether he was aware that the Middlesbrough labour exchange had refused to pay unemployment benefit to two men suspected of having been in contact with small-pox cases, in spite of the offer of the local sanitary authority to provide proper safeguards; and whether he would give instructions for the benefit and arrears to be paid to these men.—Sir ARTHUR STEEL-MAITLAND replied: In the cases referred to it was necessary to obtain a decision from the Chief Insurance Officer as to whether benefit was payable and there was also some difficulty about attendance at the Exchange, owing to possible risk of infection. The decision was in favour of the two applicants and arrangements were made for all outstanding benefit to be paid last Tuesday.

London Street Accidents.

Mr. NAYLOR asked the Minister of Transport whether the Traffic Advisory Committee was considering measures for the prevention of fatal and other accidents in the streets of London.—Col. W. ASHLEY replied: My Department is now being furnished with particulars of all street accidents in the London Traffic Area, in which vehicles are involved or which are alleged to be due to the condition of the road. All practicable steps are, and will be, taken to remove avoidable causes of risk. All the measures recommended by the London Traffic Advisory Committee for the improvement of traffic conditions in London will, I hope, tend to make the streets safer both for pedestrians and for vehicles.

Insurance Patients and Payments to Hospitals.

Mr. FORREST asked the Minister of Health whether he was aware that insured persons with no dependants were enabled at the present time to enter hospitals for treatment and then at the end to receive lump sums from friendly societies in respect of benefit, and that very often these sums were not employed to any profitable purpose, while the hospital received nothing; and whether under the circumstances he would consider an alteration of the law which would enable societies who have insured men on their books to deduct a portion of the lump sum payment due to them in these cases and make a payment from it to the hospitals for the services rendered.—Mr. NEVILLE CHAMBERLAIN replied: Except in the case of institutions main-

tained out of public funds, an Approved Society has power under the existing law to make a payment to a hospital out of the amount of benefit accruing in respect of a member, having no dependants, who receives treatment in the hospital. I have no information as to the extent to which payments are in fact made under this power, but considerable sums are paid to hospitals by Approved Societies every year out of their National Health Insurance funds, and the whole question of the relation of the hospitals to the National Health Insurance scheme is one which will no doubt be considered by the Royal Commission on National Health Insurance which is now sitting.

MONDAY, FEB. 16TH.

Medical Facilities in Palestine.

Lord COLUM CRICHTON-STUART asked the Secretary of State for the Colonies what European medical assistance was available for the families of British officials employed in the mandated territory of Palestine; and whether facilities could be given to one or more of the Government medical officers to accept as patients members of the families of such officials.—Mr. AMERY replied: The medical practitioners licensed by the Palestine Government include 30 British doctors and some 150 others of European and American extraction. I therefore see no need for any special action on the lines suggested in the second part of the question.

TUESDAY, FEB. 17TH.

Tuberculosis Statistics.

Mr. NAYLOR asked the Minister of Health the total number of cases of tuberculosis notified to local municipal dispensaries; the number of cases notified receiving institutional treatment; and the number of beds available for the cases reported during the last three years for which returns were available.—Mr. NEVILLE CHAMBERLAIN replied: As regards the first part of the question, I may point out that formal notifications of tuberculosis are made to the medical officers of health of sanitary districts, and that although the medical officers of tuberculosis dispensaries receive lists of the notifications, only a proportion of the notified cases are applicants for treatment by local authorities. The number of cases of tuberculosis notified in England and Wales during each of the last three years for which returns are available is as follows: 1921, 71,702; 1922, 69,259; 1923, 79,388. The last figure includes cases of which the medical officers of health became aware otherwise than by formal notification and is not, therefore, strictly comparable with the figures for 1921 and 1922. As regards the remaining parts of the question, the following table shows as regards England and Wales (a) the number of tuberculous persons receiving treatment in residential institutions from local authorities, and (b) the number of beds in approved residential institutions, on the dates shown:—

	(a) Persons.	(b) Beds.
Jan. 1st, 1923	15,563	20,629
" 1924	16,918	21,419
" 1925	18,158	22,086

Death-rates per 1000.

Mr. NAYLOR asked the Minister of Health the death-rate from all causes per 1000 persons for the last year for which returns were available; and the death-rate from tuberculosis per 1000 persons for the same period.—Mr. NEVILLE CHAMBERLAIN replied: For 1923, the last year for which both rates are as yet available, the figures are as follows: Death-rate from all causes per 1000 persons, 11.582; death-rate from tuberculosis (all forms) per 1000 persons, 1.062.

FOREIGN DECORATIONS.—The King has given to Dr. Alexander Jeremiah Orenstein, C.M.G., His Majesty's Royal licence and authority to wear the Cross of Chevalier de l'Ordre de la Couronne, which decoration has been conferred upon him by His Majesty the King of the Belgians in recognition of valuable services rendered by him in combating malaria in the Katanga province of the Belgian Congo.

THE IVORY CROSS: NATIONAL DENTAL AID FUND.—To mark the tenth anniversary of the organisation of the Ivory Cross a special effort is being made to enrol 10,000 new members, and an appeal has been issued signed by the Duchess of Portland and the Marquess of Salisbury who are respectively President and Chairman of the Council. The organisation provides skilled dental treatment for poor people, and since its foundation in 1914 over 100,000 patients have been treated, while there is now a waiting list of some 2000. The average administrative cost is only about 8 per cent. per annum of the income collected. Subscriptions and applications for membership should be addressed, The Marquess of Salisbury, 10, Henrietta-street, London, W.1.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, Piccadilly, W.
 THURSDAY, Feb. 26th.—4.30 P.M. *Papers to be read:*
 Prof. E. H. Starling and E. B. Verney: The Secretion of Urine, as Studied on the Isolated Kidney.
 F. Eichholst and Prof. E. H. Starling: The Action of Inorganic Salts on the Secretion of the Isolated Kidney.
 G. V. Anrep: A New Method of Crossed Circulation. (Communicated by Prof. E. H. Starling.)
 G. V. Anrep and I. de B. Daly: The Output of Adrenalin in Cerebral Anæmia, as Studied by Means of Crossed Circulation. (Communicated by Prof. E. H. Starling.)
 G. V. Anrep and Prof. E. H. Starling: Central and Reflex Regulation of the Circulation.
 K. Furusawa: Muscular Exercise, Lactic Acid, and the Supply and Utilisation of Oxygen. Part IX. Muscular Activity and Carbohydrate Metabolism in the Normal Individual. (Communicated by Prof. A. V. Hill.)
Papers to be read in Title only: A. Hunter and J. A. Dauphinee: Quantitative Studies Concerning the Distribution of Arginase in Fishes and other Animals. (Communicated by Dr. H. H. Dale.)
 A. Hunter and J. A. Dauphinee: An Approximative Colorimetric Method for the Determination of Urea with an Application to the Detection and Quantitative Estimation of Arginase. (Communicated by Dr. H. H. Dale.)
 J. J. R. Macleod and N. A. McCormick: The Effect on the Blood-sugar of Fish of Various Conditions, including Removal of the Principal Islets (Isletectomy).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, Feb. 23rd.

ODONTOLOGY: at 8 P.M.

Paper:

Mr. F. N. Doubleday: A Report upon Some Drugs and Solutions Used in Local Anæsthesia.
 Experimental evidence will be shown at 7.30 P.M.

Tuesday, Feb. 24th.

GENERAL MEETING OF FELLOWS: at 5.30 P.M.
 Ballot for Election to the Fellowship (names already circulated).

MEDICINE: at 5.30 P.M.

Clinical Meeting at the Westminster Hospital.
 Tea will be served at 5 P.M.

Wednesday, Feb. 25th.

COMPARATIVE MEDICINE: at 5 P.M.

Paper:

Dr. Nathan Raw: Immunisation against Tuberculosis in Man and Animals.

Thursday, Feb. 26th.

EPIDEMIOLOGY AND STATE MEDICINE: at 5.30 P.M.

Paper:

Dr. William Robertson (M.O.H. Edinburgh): The Preventive Control of Diphtheria.

UROLOGY: at 8.30 P.M.

Papers:

Dr. Archer and Dr. Robb: The Tolerance of the Body for Urea in Health and Disease.
 To be followed by a Discussion in which Dr. Hugh MacLean, Dr. G. A. Harrison, and Dr. de Wesselow will take part.
 Mr. K. McFarlane Walker: A New Diathermy Punch Operation for Prostatic Obstruction.

Friday, Feb. 27th.

STUDY OF DISEASE IN CHILDREN: at 5 P.M. (Cases at 4.30 P.M.)

Cases will be shown by Dr. W. M. Feldman, Dr. Bernard Myers and others.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 23rd.—8.30 P.M., Sir G. Lenthal Cheatle: The Early Stages of Pathological Hyperplasia in the Breast, with special reference to Cysts and Their Danger.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, Feb. 27th.—8.30 P.M., Continuation of Discussion on The Vaccine Therapy of Gonococcal Infections.
 Papers by Prof. J. W. H. Eyre and Dr. David Thomson.

SOCIETY OF MEDICAL OFFICERS OF HEALTH (MATERNITY AND CHILD WELFARE GROUP), 1, Upper Montague-street, Russell-square, W.C.

FRIDAY, Feb. 27th.—5.30 P.M., Mr. Somerville Hastings: Measures to Prevent Aural Defects.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Feb. 23rd.—5 P.M., Dr. G. W. De P. Nicholson: The Nature of Tumour Formation.

WEDNESDAY.—5 P.M., Second Lecture.

FRIDAY.—5 P.M., Third Lecture.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 23rd, to SATURDAY, Feb. 28th.—NORTH EASTERN POST-GRADUATE COLLEGE (Prince of Wales's General Hospital, Tottenham, N.). Intensive Course in Medicine, Surgery, and the Special Departments. Second week. With the exception of Saturday, work will begin at 10.30 A.M. and continue until 5.30 P.M., and will include Demonstrations, Medical and Surgical Clinics, Operations, and opportunity for study in the Special Departments.—LONDON LOCK HOSPITAL, 91, Dean-street, W. Comprehensive Course, Clinical work daily, and Lectures.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, Leicester-square, W.C. Demonstrations daily in the various departments. Pathological Demonstrations arranged for, and Tuesday and Thursday Special Lectures. Tickets for this particular Course from the Fellowship.—LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, N.W. Tuesday and Thursday, 2 P.M., Clinical Demonstrations by Dr. G. C. Low and Dr. Manson-Bahr.

UNIVERSITY OF LONDON.

WEDNESDAY, Feb. 25th.—5 P.M. (in the Lecture Hall of the Royal Society of Medicine, 1, Wimpole-street, W.). Dr. R. Cruchet, Professor of Pathology and General Therapeutics in the University of Bordeaux: The Relation of Paralysis Agitans to the Parkinsonian Syndrome of Epidemic Encephalitis. (In English.)

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Dr. Scott Pinchin: Medical Out-patients. 2 P.M., Mr. Addison: Surgical Wards.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—11 A.M., Medical Registrar: Medical Wards. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients.

THURSDAY.—11 A.M., Sir Henry Simson: Gynaecological Wards. 12 noon, Mr. Sinclair: Abdominal Surgery (lecture). 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

FRIDAY.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Viasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 P.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: FEB.—MARCH, 1925.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, Feb. 23rd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Myasthenia Gravis: Dr. Riddoch.

TUESDAY, Feb. 24th.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Symptomatology of Cerebral Tumours: Dr. Grainger Stewart.

THURSDAY, Feb. 26th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Methods of Testing the Eighth Nerve (in O.P. Department): Mr. Just.

FRIDAY, Feb. 27th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Common Causes of Recurrent Vertigo: Mr. Sydney Scott.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.

THURSDAY, Feb. 26th.—12 noon, The Cerebro-Spinal Fluid Physiology and Pathology: Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

MONDAY, Feb. 23rd.—12 noon, Motor System, Pyramidal and Extra-Pyramidal: Dr. Hinds Howell.
 The Fee for this Course will be £2 2s.

Dr. H. J. Macbride will give a COURSE OF EIGHT CLINICAL DEMONSTRATIONS chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM, in the Wards at 10 A.M. on Tuesdays and Fridays, if sufficient entries are received. The Fee for this Course will be £2 2s.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.

WEDNESDAY, Feb. 25th.—3.30 P.M., The Optic Nerve: Mr. Leslie Paton.

Applications for this Course should be made early. Fee £5 5s. if taken as a separate Course, or £3 3s. if taken with the General Course.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M. or at such other times as may be announced.

Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course.

Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.

J. G. GREENFIELD, Dean of Medical School.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Feb. 26th.—4 P.M., Dr. Poynton: Arthritis in Childhood.

NORTH-EAST LONDON POST-GRADUATE COLLEGE

Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 23rd.—4.30 p.m., Dr. H. W. Barber :

Principles of Treatment of Skin Disease.

TUESDAY.—4.30 p.m., Dr. J. Metcalfe : X Ray Findings in

Disease of the Heart and Aorta (lantern).

WEDNESDAY.—4.30 p.m., Dr. P. Manson-Bahr, D.S.O. :

The Diagnosis of the Dysenteries.

THURSDAY.—4.30 p.m., Mr. A. E. Giles : Sterility.

FRIDAY.—4.30 p.m., Mr. H. D. Gillies, C.B.E. : The Role

of Plastic Surgery in Civil Practice (lantern).

Daily : Special Post-Graduate Course : Demonstrations,

Cliniques, Operations.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL POST-

GRADUATE LECTURES, Marylebone-road, N.W.

THURSDAY, Feb. 26th.—5 p.m., Mr. L. C. Rivett : Albumin-

uria in Pregnancy.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, Feb. 24th.—5 p.m., Dr. S. E. Dore : Alopecia.

THURSDAY.—5 p.m., Dr. Haldin Davis : Leukemia Cutis.

Mycosis Fungoides.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADU-

ATE LECTURE (at Whitworth-street West Branch).

FRIDAY, Feb. 27th.—4.30 p.m., Dr. Fletcher Shaw : Con-

tracted Pelvis.

ROYAL INSTITUTION, Albemarle-street, W.

THURSDAY, Feb. 26th.—5.15 p.m., Sir Arthur S. Woodward :

First of Two Lectures on Dinosaurs.

FRIDAY.—9 p.m., Sir James Irvine : Sugars from Standpoint

of the Organic Chemist.

SATURDAY.—3 p.m., Sir Ernest Rutherford : First of Four

Lectures on the Counting of Atoms.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH.

TUESDAY, Feb. 24th.—4 p.m., Prof. Price : Renal Insuffici-

ency and Surgical Procedure. Discussion.

THE PEOPLE'S LEAGUE OF HEALTH.

Lectures on What We Should Eat and Why, at the Medical

Society of London, 11, Chandos-street, W.

WEDNESDAY, Feb. 25th.—6 p.m., Prof. R. H. A. Plimmer :

Diseases Caused by Badly Chosen Diets.

Appointments.

BENN, E. C., M.B., Ch.B. Liverp., has been appointed House

Physician at St. Luke's Hospital, Bradford.

St. Thomas's Hospital: PATRICK, C. V., M.B., B.Ch. Cantab.,

F.R.C.S. Eng., Surgical Registrar: ARCHER, E. C.,

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal United Hospital.—Hon. Anesth.

Brighton, New Sussex Hospital.—H.S. £50.

Bristol General Hospital.—House Appts. All at rate of £80.

Bristol Royal Infirmary.—Obstet. and Cas. H.S.'s. Each £100.

H.P.'s and H.S.'s. Each £80. Also Dent. H.S. £116.

British Hospital for Mental Disorders, &c., 72, Camden-road,

N.W.—Hon. Phys.

Bury and District Joint Hospital Board.—Res. Asst. Med. Supt.

£400.

Rury Infirmary.—Jun. H.S. £150.

Cairo Egyptian Government, Dept. of Public Health.—Health

Expert and Director of Public Health Labs. Each L.E. 1450.

Also First Bacteriologist in Pub. Health Labs. L.E. 900.

Cambridge, Addenbrooke's Hospital.—H.S. at rate of £130.

Cardiff, Welsh National School of Medicine.—Asst. Lecturer in

Dept. of Phys. £400.

Croydon General Hospital.—Jun. H.S. £150.

Ealing Borough.—Asst. M.O.H. £600.

Hampstead, New End Hospital.—Sen. and Jun. Res. Asst. M.O.'s

at rate of £250 and £150 respectively.

Hospital for Sick Children, Great Ormond-street, W.C.—Surg. Reg.

£300.

Hospital for Women, Soho-square, W.—Res. M.O. £100.

Leicester Royal Infirmary.—Two Surg. Dressers. 10s. 6d. per

week.

London Temperance Hospital, Hampstead-road, N.W.—Dermato-

logist.

Manchester, Ancoats Hospital.—Res. M.O. and Pathological

Reg. at rate of £175 and £100 respectively.

Manchester, Christie Hospital.—Cancer Research Worker. £500.

Manchester City.—Asst. Tub. O. £620 19s. 9d.

Manchester Royal Infirmary.—R.M.O. and Asst. M.O. at rate of

£200 and £100 respectively.

Manchester, Royal Manchester Children's Hospital.—Asst. M.O.

at rate of £150. Also Res. Surg. O. at rate of £80.

Manchester, Salford Royal Hospital.—H.S. and Cas. H.S. Each

at rate of £150.

National Hospital for the Paralyzed and Epileptic, Queen-square,

W.C.—Asst. Ophth. S.

Newcastle-upon-Tyne, Hospital for Sick Children.—Sen. and Jun.

R.M.O.'s at rate of £120 and £100 respectively.

Newcastle-upon-Tyne, Princess Mary Maternity Hospital,

Jubilee-road, City-road.—Asst. Res. M.O. at rate of £40.

Newport Education Committee.—Asst. Sch. M.O., &c. £600.

Nottingham General Hospital.—Pathologist. £350 and private

fees allowed.

Portsmouth Royal Hospital.—Sen. H.S. at rate of £200.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—

Two Asst. Res. M.O.'s. Also Sen. Res. M.O. At rate of £80

and £100 respectively.

Royal Chest Hospital, City-road, E.C.—Phys. Also Hon.

Radiologist.

Royal National Orthopaedic Hospital.—H.S. at rate of £150.

Royal Northern Hospital, Holloway, N.—Asst. Radiologist. £150.

St. Stephen's Hospital, 369, Fulham-road, S.W.—Third Asst.

M.O. £300.

Salford Union Infirmary, Hope, Pendleton, near Manchester.—

Asst. Res. M.O. at rate £275.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—

S. to In-patients and S. to Out-patients.

Sheffield, Jessop Hospital for Women.—Gynaecol. and Mat.

Dept., Hon. Gen. P.

Southampton County Borough.—Asst. M.O.H. £600.

Stoke-on-Trent, North Staffordshire Infirmary.—H.P. £150.

University College Hospital, Gower-street, W.C.—Obstet. Phys.

Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £100.

Western Ophthalmic Hospital, Marylebone, N.W.—Sen. and Jun.

H.S.'s at rate of £150 and £100 respectively. Also Hon.

Dental S.

Wilkesden General Hospital, Harlesden-road, N.W.—Hon.

Radiologist.

Yorkshire Orthopaedic Hospital, Kirbymoorside.—Res. Orthop. S.

£500.

Births, Marriages, and Deaths.

BIRTHS.

SPARROW.—On Feb. 8th, at Wayside, Watford, the wife of

E. C. Sparrow, M.B., B.Ch., of a son.

STARKIE.—On Feb. 14th, at St. George's-road, S.W., the wife

of Dr. Richard P. Starkie, of a son.

STEPHENS.—On Feb. 8th, at Terrace-houses, Richmond, Surrey,

Celia Mary Colquhoun Macneil, M.B., Ch.B., the wife of

Cromwell A. Stephens, of a daughter.

MARRIAGES.

MACWATT—SKETCHLEY.—On Feb. 14th, at Holy Trinity Church,

Exmouth, John Macwatt, M.B., Morelands, Duns, Berwick-

shire, to Dorothy Gertrude Powys, younger daughter of the

Rev. and Mrs. E. Powys Sketchley, of Exmouth.

DEATHS.

DUGON.—On Feb. 12th, at the School of Tropical Medicine,

Endleigh-gardens, N.W., Thomas Henderson Dugon,

M.R.C.S., L.R.C.P., Assistant Director of Medical Services,

Nigeria.

JONES.—On Feb. 16th, at Hyde Park-gate, passed away peace-

fully in his sleep, Dr. Evan Jones, J.P., late of Aberdare,

aged 88.

KLEIN.—On Feb. 9th, at Wilbury-villas, Hove, Prof. E. E. Klein,

M.D., F.R.S., formerly of Bart.'s, aged 80.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of

Births, Marriages, and Deaths.

INDEX TO "THE LANCET," VOL. II., 1924.

THE Index and Title-page to Vol. II., 1924, which was completed with the issue of Dec. 27th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

Notes, Comments, and Abstracts.

THE TRAINING OF HEALTH VISITORS.

A TRANSFERENCE of the authority for the payment of exchequer grants in aid of the training of health visitors from the Board of Education to the Ministry of Health takes place on April 1st, and a Memorandum (101/M.C.W.) issued from the Ministry explains certain changes which will be made in the regulations. It has been decided to approve for the payment of a grant of £15 a whole-time course of training in public health work lasting for a minimum period of six months, provided the student is a trained nurse who has either obtained, or declared her intention of obtaining, the certificate of the Central Midwives Board.

Students who are not trained nurses must attend courses of training of two years' duration at recognised institutions, and a grant of £20 each year will be payable in respect of students who have obtained, or intend to obtain, not less than six months' training in a hospital, and also the certificate of the Central Midwives Board.

Students who receive grants will be required to enter for an oral and written examination conducted by a body approved for this purpose; successful candidates will be given a health visitor's certificate. The course must include theoretical instruction in: (1) Elementary physiology and the structure of the body; (2) personal and domestic hygiene, general hygiene and sanitation; (3) infectious and communicable diseases, including tuberculosis and venereal diseases; (4) maternity, infant and child welfare; (5) school medical service; (6) sanitary law and government, elementary economics, and social problems; (7) the principal legal enactments and regulations connected with the above-mentioned subjects. The corresponding practical instruction must be conducted, so far as practicable, in coöperation with the Public Health Department of the local authority for the area in which the course is given.

This examination will also be open to women who have given satisfactory service as whole-time health visitors for a period of five years without any special course of instruction. After April 1st, 1928, the appointment of a woman for the first time as a whole-time officer of a local authority with health visiting duties will not be approved unless she has obtained a health visitor's certificate.

In a letter (Circular 557) dated Feb. 9th, addressed to local authorities carrying out maternity and child welfare schemes, the Minister calls attention to these regulations and also to the desirability of providing occasional "refresher" courses for those who are already engaged in health visiting. He is prepared to approve the payment by local authorities of the reasonable expenses of their health visitors (including fees, maintenance, and travelling expenses) in attending whole-time courses lasting from two to four weeks and designed with a view to extending both their practical and theoretical knowledge. Reasonable expenditure incurred in respect of short part-time courses will also be eligible for grant. It is pointed out that, since new entrants to the profession of health visiting will be required to devote 3½ or 4 years to their training for this work, the salaries offered should be sufficient to attract and retain efficient qualified women.

INTOLERANCE TO A DENTURE.

To the Editor of THE LANCET.

SIR,—The letter from "Medico" concerning his denture which appears in your issue of Jan. 10th, has been brought to my notice. I would advise him to take a small pellet of wool in a pair of ordinary dressing forceps and gently rub it against every spot on his palate which the denture covers. He may find one which is hypersensitive and induces retching when touched. If so, the denture should be so constructed as not to touch the spot or its immediate neighbourhood. I have had such cases. The remedy is simple.

I am, Sir, yours faithfully,

Devonshire-place, W., Feb. 10th.

PERCY EDGELOW.

THE CRIPPLES' JOURNAL.

THE third number of the interesting quarterly entitled the *Cripples' Journal* fulfils the promise of the previous issues. One of the chief objects of the publication is to arouse and keep awake a sense of the duty of the public to provide adequately for the cure and care of all the cripples in this country. We agree with most of the views set out in the editorial note on "Converting the Public" with which this issue opens, but we cannot subscribe to the statement that "the ancients knew considerably more about massage, cleanliness, exercise and sunlight than we do." The Rev. Ratcliffe Barnett and Mr. W. A. Cochrane, of Edinburgh, contribute an informing article on the Cripple Child in Scotland. We deprecate the use of the substantive "Cripple" as an adjective throughout this and

other articles; crippled is the correct epithet and the substitution of "cripple" is likely to cause a sensitive reader to have what these writers would presumably call a "trouble" mind. Mr. Archibald Irwin, of Belfast, writes an article on the Crippled Children of Ireland, which deals exclusively with conditions in the north of Ireland. Mr. Rocyn Jones's first instalment of *An Historical Review of Orthopaedic Surgery* promises well for the interest of the second part in the next number. Titania's Palace is described by Sir Neville Wilkinson. Miss A. G. Hunt continues her humorous history of Boschurch and the secretary of the Royal National Orthopaedic Hospital gives an account of the history of that institution with interesting photographs of its country branch at Brockley Hill. Leasowe Hospital for Children is described by its senior medical officer and the Codrville Institute by Mrs. Hey-Groves. The number ends with a useful report of the Central Committee for the Care of Cripples, giving the results of inquiries made in 40 counties as to the provision that is or soon will be available in them. With few exceptions the counties and provincial cities seem to be awaking to their responsibilities in this matter.

A WIRELESS MAGAZINE.

WIRELESS entertainments are being increasingly used as a means of modifying the monotony of convalescence, and, in some cases, as aids to medical treatment, consequently among our hospital populations there are many who take an interest in wireless publications. From Messrs. Hiffe and Sons, Ltd., Dorset House, Tudor-street, London, E.C., we have received a copy of the *Wireless World and Radio Review*, described as a paper for every wireless amateur. This publication, which was established over 12 years ago, has now been taken over by Messrs. Hiffe and Sons and has been issued in an enlarged and more attractive form. In addition to articles of a practical nature for the beginner and the advanced amateur the present issue (Feb. 11th), beginning a new volume, contains a talk by Dr. J. A. Fleming, F.R.S., the inventor of the wireless valve, on the training of the radio engineer.

AN APPEAL FOR BLIND DEFECTIVES.

AT the present time no provision exists for the indigent blind who come under the category of defectives. To remedy this state of things the Ministry of Health specially asked the Braille and "Servers of the Blind" League, of which Her Highness Princess Marie Louise is Patroness and Dame Ellen Terry is President, to help in the matter, and the first "Ellen Terry" National Home in Reigate for blind defective children up to the age of 10 years is almost ready for occupation. A second home for older children is in contemplation. In order that the work may be successfully and quickly accomplished a "Daffodil Day" is being organised throughout the Metropolitan area next Saturday (Feb. 28th), and an appeal is being made for helpers, for the loan of motor-cars, and for donations. Offers of assistance should be addressed to Mr. Clifford Newton, the organising secretary, 3, Upper Woburn Place, London, W.C. 1.

PREVENTIVE MEDICINE AND BUSINESS PROSPERITY.

RECOGNISING the importance of good health to its business, the Metropolitan Life Insurance Company has long been a generous supporter of public health work in Canada and the United States. Its latest benevolent act is the giving of 15,000 dollars to the Canadian Social Hygiene Council for the extension of its child welfare and educational activities. This Council, of which Dr. Gordon Bates is the general secretary and founder in Canada, will now be able to extend its fight against venereal diseases to the rural as well as the urban communities in Canada and to put an expert in charge of the educational policy of the Council who will coöperate with a voluntary advisory committee of physiologists, psychologists, biologists, hygienists, and educationists, to work out an educational scheme for the young which will be national in scope and acceptable in all parts of the Dominion. Two appointments have been already made. Mr. A. D. Hardie, an English headmaster of wide experience, will take charge of some of the work of the educational department of the Council, and Dr. L. A. Pequegnat will become organiser for the eastern provinces.

ERRATUM.—In THE LANCET of Feb. 7th, p. 318, we announced that Glasgow University students in a carnival on Jan. 17th in aid of local infirmaries and charities collected over £700. A Glasgow correspondent points out that the figure should be £7000, not £700, and adds the amusing comment that the lesser sum could not possibly have been reported to us by any citizen who fell into the persuasive hands of the student "highwaymen" on that day. Such was the energy of the collectors' methods that even the very large total of £7000 need not have surprised us.

Lettsomian Lectures

ON

WOUNDS AND OTHER INJURIES IN THEIR MEDICO-LEGAL ASPECT.

Delivered before the Medical Society of London

By SIR BERNARD H. SPILSBURY, M.B.,
B.Ch. Oxf., M.R.C.P. Lond.,

LECTURER IN MORBID ANATOMY AND HISTOLOGY, ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE; HON. PATHOLOGIST TO HOME OFFICE.

LECTURE I.

As it is, I fear, impossible to deal comprehensively with this subject I propose to give an account of my own experience of the last 20 years, and I have endeavoured to extract from the material at my disposal especially those facts and conclusions which seem to have a general application to medico-legal problems, although I realise the disjointed effect entailed by this method of treatment.

I have collected about 600 cases, grouped for convenience of treatment under headings representing the different varieties of injury.

An apology may be thought necessary for dealing with a subject so elementary, in some of its aspects, as bruises, but medical evidence in these cases is so often based on a misunderstanding of the nature of the processes entailed, that I consider it advisable to apply physiological principles to the problem presented by their formation.

BRUISES.

A contusion, or as it is commonly called, a bruise, is a crushing injury produced either by excessive pressure upon the surface of the body, or by violent contact with an object which is relatively incompressible, and which is of such a form as to produce no gross injury to the surface. The crushing force damages the fat in the skin and subcutaneous tissue rather than the dense fibrous tissue of the cutis vera, tearing the capillaries and veins in the crushed tissue. As soon as the force ceases to act the pressure within the blood-vessels causes blood to issue from the torn ends, and forces it slowly between the elements of the damaged tissue, producing a diffuse infiltration which extends into surrounding parts. Loose cellular connective tissues, muscles and viscera lying beneath the crushed area may be the seat of similar hæmorrhagic infiltration. In parts, such as the eyelids and vulva, where the skin has a loose texture, infiltration of the damaged tissue by blood occurs more readily, and bruising develops rapidly; where the deeper part of the skin is more densely fibrous, and fat is scanty or absent, as in the palm of the hand, greater violence is required to produce a contusion, and the amount of blood effused is small.

When the local application of violence is extreme, the soft tissues beneath the skin may be pulped and completely disorganised, and blood-vessels of larger size, including arteries, are torn across. The resulting hæmorrhage is more rapid and profuse, and instead of infiltrating it pushes aside the crushed tissue to form a cavity filled with blood—a hæmatoma. A very similar effect is produced by a foreign body such as a bullet tearing its way through the tissues; if its progress is arrested by the skin a bruise speedily forms in the subcutaneous tissues around it. It is the causative agent—violence—which differentiates contusions from other conditions of hæmorrhage into the tissues, due to excessive pressure within the blood-vessels, or to disease of the blood-vessels and tissues.

It is unnecessary here to describe the changes which take place in contusions, and the processes of absorption and restitution in the injured areas. If the violence is maintained until death, and for a

short time afterwards, there may be no escape of blood from the torn blood-vessels, the only effects of the crushing force being some pitting of the skin, and perhaps slight softening of the damaged area; usually, however, a little blood escapes at the margin of the crushed area and the hæmorrhage becomes more evident if the compressing object alters its position. This explains the slight amount of bruising which may result from the pressure of the fingers of an assailant upon the neck of the victim in a fatal case of throttling, although the violence may have been so great as to have led to the production of hæmorrhage in the loose cellular tissue between the larynx and the spine.

There are persons who bruise very readily as the result of pressure which in others would have no effect. A peculiar fragility of the blood-vessels has been advanced in order to explain this condition, but a more likely explanation is that these persons take insufficient exercise and consume in their food a large amount of fats having a low melting-point, such as butter; as a result the fat deposited in the subcutaneous tissues has a melting-point lower than the average, and at the body temperature the fat would be more fluid and the tissues more easily crushed. A lady who was unable to play tennis owing to the ease with which she bruised and who, during the war, led a more active life, lost the condition. The changes in diet under war conditions may have contributed to this result. The trained athlete can receive fairly severe blows without developing bruises, and the designation "hard" may well be applicable to his skin as well as to his muscles.

A bruise inflicted shortly before death which is not visible on the surface of the body may become apparent a few hours or several days after death. This is due not to any appreciable addition to the blood in the contused area after death, but to a more rapid hæmolysis in the stagnant blood as a part of post-mortem changes; there is no circulation to carry away the pigment, and the tissues are dead and cannot deal with it. The pigment diffuses locally, producing a stain in the surface, dark red at first, but changing sometimes to a bright red colour from absorption of oxygen through the skin; or an area of dark green putrefactive discoloration appears over a deep bruise before the skin around it is changed.

Since the development of a contusion is dependent upon the maintenance of the circulation it follows that as soon as the heart's action is arrested in death the arterial pressure falls, and the circulation slows down and is soon completely arrested. The production of a contusion then becomes impossible.

Observations¹ upon the circulation in the retina at the time of death have shown that the fall of arterial pressure is so rapid that within half a minute of the heart ceasing to beat the blood-stream may be reversed in the arteries, flowing backwards more readily than it passes through the capillaries. This phenomenon is probably peculiar to the eyeball and is accounted for by the ocular tension, but the observations demonstrate the rapidity with which the circulation runs down after death, and render it certain that 5 or 6 minutes after the heart has ceased to function the circulation will be at an end, and the pressure will be the same in the blood-vessels and tissues. Two minutes after death no appreciable bruising occurs and the amount of blood effused, when death follows immediately upon the infliction of the injury, will be slight in comparison with the amount when the injured person survives.

I have seen several cases in which death resulted from the shock of multiple contusions.

In one, a woman about 45 years of age, who had been brutally assaulted and who was found dead in her apartment, six bruises were found on examination of the body; three of these situated on the face and head were of large size and were caused by severe crushing. There were no open wounds upon the body, little blood had been lost, and there was no disease to account for the death.

¹ C. H. Usher: *Ophthalmic Review*, 1896, xv., 339.

CRUSHING INJURIES OF THE CHEST AND ABDOMEN.

The data upon which this section of the lecture is based have been obtained by analysis of the post-mortem records of 184 cases of this nature. These cases, taken mainly from my hospital records from 1905 onwards, include many street accidents from the time when motor vehicles began to predominate, and they therefore indicate the serious character of the injuries produced by fast and heavy traffic. The injuries were so grave that many were dead or at the point of death on reaching hospital, and in over 40 per cent. the nature of the accident is not recorded: of the remaining 103 cases 60 per cent. were street accidents. Other causes include falls from a height, crushes by falling debris, by railway trains, and in lift accidents, and by severe blows on the chest and abdomen by cart-poles, kicks by horses, &c.

An examination of the results shows that in one-half of the cases no external injury—not even a bruise or the mark of a wheel—was present at death on the surface of the chest or abdomen; in a large proportion death was due solely to injuries of the organs in these regions, and ribs were fractured in 75 per cent. of the cases. Recorded cases of injury of the chest and abdomen include many in which no external injuries were seen, and I was surprised to find that they occurred in so many of the cases in this series.

Crushing Injuries of the Chest.

The *lungs* give the highest figure of all the organs, being lacerated or severely bruised in 104 cases; in most of them the injury was caused by the penetration of fractured ribs, but serious injuries had been produced in several instances by extreme flattening of the chest without fractures in some of the younger subjects; in three of these cases one lung had been completely torn away from its attachments.

In contrast with the lungs, the injuries of the *heart* and great vessels in the chest were found only in 40 cases; this figure corresponds closely with that of fractures of the sternum (42 cases), although the two occur together only 14 times in these records. The injuries of the heart range from bruising to extensive laceration, and in two cases the heart had been completely torn away, and was lying free in one of the pleural cavities.

The *main blood-vessels* were injured in several other cases, rupture of the aorta being found in four.

One of these was in an elderly lady who fell down the steps at a railway station, and who, although severely shaken, was able to return home alone, where she died suddenly an hour afterwards. She was found to have a laceration three-quarters of an inch long through the whole thickness of the aorta, immediately above the valve, where the artery was slightly thinner than the normal; the blood which escaped from the vessel had forced its way slowly through the epicardial fat and into the pericardial cavity at the level of the auriculo-ventricular groove. As in some other cases the laceration strikingly resembled a clean cut in the vessel wall, the only difference being that the tunica adventitia was dissected away by the issuing blood rather than cut.

Crushing Injuries of the Abdomen.

Of the abdominal viscera the *liver* is the organ which is most frequently damaged. Injuries ranging from severe bruising to extreme laceration were found in 84 cases; in several the organ was torn into two halves, or a large piece completely separated. The injuries were as frequent on the left as on the right side, but the more serious were usually in the right lobe, many being situated near the falciform ligament or at the right extremity of the organ. The frequency with which the liver suffers when the abdomen is compressed is due to its large bulk and to its position—lying across the spine, against which it is crushed when the pressure is from the front. In none of the cases was the liver softened by disease, but on two occasions cirrhosis was found.

The *spleen* is next in order of frequency, and it suffered in 46 cases. Situated under the left ribs, it is poorly protected when the abdomen is severely crushed or is struck upon the left side. In none of

the cases was there a condition of enlargement of the organ such as accounts for the frequency of rupture in tropical countries.

There are only 30 cases of injury to the *kidneys* in this series; in two only were both organs involved. Their protected position no doubt accounts for the less frequent damage, which occurs chiefly in persons who have been run over, one kidney being crushed against the spine as the wheel mounts the abdomen, the other escaping as the wheel passes off. The direction in which the wheel crosses the body may thus be indicated.

The *stomach*, *duodenum*, and *pancreas* can with advantage be considered together. Owing to their close anatomical relations these organs are likely to suffer in the same class of injury, especially when the compressing force acts over a comparatively small area, as, for example, the pole of a cart crushing these structures against the spine. In other crushes the liver protects these organs to some extent, but the stomach is occasionally lacerated when the abdominal contents are forcibly pressed to one side in those who are run over. Lacerations were found in the stomach in 16 cases, in the duodenum in 12, and in the pancreas in 18 cases. In only one case of pancreatic injury did the patient survive long enough for fat-necrosis to develop.

The *intestines* and *mesentery* are represented in the series by 34 cases, 23 tears in the intestine and 11 in the mesentery. A large proportion of the lacerations in the small intestine are situated at or just below the duodeno-jejunal junction, and their frequency in this area is due probably to the fixed position of this part of the intestine, causing it to be more readily crushed against the spine, or to its being torn when the intestines are pushed bodily over to the right side of the abdomen; several of the wounds had the appearance of tears rather than crushes, the muscular coat being lacerated over a larger area than the mucous membrane. It was noted in a number of these cases that the contents of the intestine had not escaped in appreciable amount into the peritoneal cavity, and it is probable that peristalsis was arrested by the shock resulting from compression of the abdomen.

Lastly, laceration of the *diaphragm* was found in 13 cases in the series, the injury being met with in association with other serious abdominal injuries, the liver having been crushed in almost all of them. In the majority the tear was extensive and in six cases abdominal viscera had passed into the pleural cavity, the stomach and spleen being the organs most commonly found there.

WOUNDS PRODUCED BY PROJECTILES.

Wounds produced by projectiles discharged from firearms present the characters of lacerated wounds, but their appearances are very varied, depending upon the class of weapon, whether modern rifle, shotgun, or short-barrelled pistol; and in any one of these classes the penetrative power of the projectile and the extent of the damage produced depend upon its weight, shape, and composition, on the length of the barrel of the weapon, and on the amount and nature of the charge. Thus the penetrative power of a bullet fired from a small automatic pistol is far less than that of a larger and longer-barrelled service revolver. I have collected 32 cases of gunshot injuries; most of them occurred in London, and the weapon, at any rate before the war, was generally a small revolver, and was used at short range.

Effects Produced by Passage of Projectiles Through the Tissues.

This class of injury affords an interesting study, both of the effects produced by the passage of projectiles through the tissues, and of the circumstances in which the injuries have been inflicted. If discharged within a short distance of the body there may be surface indications from which the distance of the weapon can be accurately determined, and the path of the projectile through the body enables the exact position of the weapon in relation to the victim to be deter-

mined, and may give valuable information as to the medico-legal significance of the wound. When the projectile penetrates another object after traversing the body it may be possible to reconstruct exactly the circumstances in which the weapon was discharged, whilst the firm grasp of the weapon in the hand of the victim after death gives a clear indication of a self-inflicted injury.

When a weapon is discharged near the body the external markings are seen principally upon the skin and clothing around the entrance wound. They vary with the type of cartridge and the nature and amount of the charge and are less distinct when smokeless powder is used. The changes produced by black powder are due to flame when the discharge is very close, to smoke for a rather longer distance, and to unconsumed powder at a still greater range. Flame may singe or set fire to clothing, singeing the hair and slightly burning the skin, with the formation of a glazed, brown, parchment-like area after death. Smoke, when the discharge is fairly close, produces a uniform black deposit, and grains of unconsumed powder expelled from the weapon behind the projectile are carried for a distance possibly of several feet, spreading like small shot, and with such force that they are embedded in the skin and clothing, and produce characteristic tattooing. The pattern produced round an entrance wound in a given case may be reproduced by experiment, using the same weapon and cartridges of the same manufacture; the distance at which the weapon has been discharged may thus be estimated with a fair degree of accuracy.

In cases of self-inflicted injury blackening and splashes of blood may be found upon the hand used to steady the weapon at the muzzle end. The external indications of a near discharge may be absent when the muzzle of the weapon is pressed firmly against the skin, the gases of the discharge, the flame, smoke, and powder grains all following the track of the bullet into the body. In one case there were no external marks excepting a slight blackening of the edge of the wound on the right temple, but the skin was separated from the pericranium round the entrance wound over an area measuring 2 by 1½ in. There was smoke-blackening of the wall of the cavity and of the outer surface of the dura mater where it had been detached from the skull; along the track of the bullet in the right cerebral hemisphere powder grains were embedded and the track was blackened by smoke. In another case the escaping gases had stripped up the skin, blackening its deep surface, and had produced four splits radiating from the edge of the wound; the exposed surface of the dura mater was also blackened.

Apart from splitting of the skin produced by the gases of the discharge the wound of entrance is generally small, circular when the weapon is discharged at right angles, and oval in shape when the bullet has entered obliquely; the margin of the wound may be inverted, though this is by no means constant.

The wound of exit is often larger and more irregular, especially when the bullet has passed through bone; this is due to deformation of the bullet or to laceration of the skin by fragments of bone expelled by the projectile. Multiple exit wounds may be so produced—and this is more frequently seen when the projectile is large and travels at high velocity, splintering the bone at some distance from the skin. The skin at the margin of the exit wound is often everted.

Bullet Wounds in the Head.

Suicidal bullet wounds in the head are most frequently found in the temple. I have examined six cases in which the entrance wound was in the right temple, another in which the bullet entered above and behind the right ear, running somewhat forwards—an unusual direction for a suicidal injury—and another where the entrance wound was on the forehead close to the middle line. In every case the bullet passed through the cranial cavity, producing openings in the bone in which the edges were distinctly bevelled as the result of more extensive fracturing of the table

on the side on which the bullet emerged; the only exceptions were those in which the skull was so thin that the tables merged into a single compact shell.

In all but one of the cases the skull also showed *bursting effects*, due to the passage of a projectile of high velocity through a closed cavity. The most usual manifestation of this effect was in the orbital plates of the frontal bones and the cribriform plate, which were extensively fractured even when the bullet had not passed near them. Injury of the orbital fat consequent upon these fractures led to the appearance of bruises in the upper eyelids of those who survived for a few hours. Less frequently the roof of the tympanum was fractured. The bursting effect was also shown by the presence of fissured fractures partly encircling the head.

In one case a fracture extended from the entrance wound on the forehead round the right side of the head above the ear to the exit wound in the right occipital region. In another case the bullet had passed across the skull high up and a fracture at a lower level extended horizontally round the head on each side from a point above and behind each ear, traversing in front the anterior ends of the orbital plates. In a third case the entrance wound was above and behind the right ear, and the exit wound immediately above the left ear; three fissured fractures extended from the entrance wound, one running directly backwards and around the back of the head to the left side, a second crossing the top of the head to the exit wound, and a third running forwards and downwards along the right side of the skull, crossing the front ends of both orbital plates. The skull was encircled by fractures in three-quarters of its circumference. An interesting feature in this case was the wide separation up to a quarter of an inch of the fractures; beneath these fractures the brain was marked by lines of superficial bruising where it had been forced into the gaps by increased intracranial pressure.

None of the cases showed such marked bursting effects as have been recorded, where the skull has been smashed into many fragments.

A most remarkable case, and I believe a very rare one, was related to me by a medical friend, who during the retreat from Mons saw a guardsman lying at full length with the top of his skull raised and turned backwards, almost as clean as if it had been sawn through in the post-mortem room, and with the cranial cavity completely empty; the brain, which appeared to be uninjured, was lying a short distance away. He had been struck by a bullet in the middle of the forehead just above the root of the nose.

One suicide fired a revolver below his chin, the bullet passing through the floor of the mouth, the tongue, and the nose, and lodging beneath the skin at the inner end of the eyebrow. The weapon had also been fired into the chest, the bullet traversing the left lung and leading to a fatal result 12 days later from empyema and broncho-pneumonia.

In three cases the weapon was discharged through the roof of the mouth, the bullet passing through the palate; two were clearly suicidal cases, and in one of them two bullets had been fired, one lodging in the antrum of Highmore, the other penetrating the base of the skull and traversing the brain. The third was an example of self-inflicted injury very similar to the last two, but the coroner recorded a verdict of accidental death. A young man was found lying on his back on the floor of his bedroom, dead, the sound of the discharge of a firearm having been heard a few minutes previously. He lay opposite a looking-glass, his left hand was in his pocket, and the revolver containing one empty cartridge case was found in a closed drawer. He had shot himself through the roof of the mouth, the bullet passing through the hard palate in the middle line and vertically upwards, smashing the nasal septum and the cribriform plate, passing through the cranial cavity between the frontal lobes; the bullet was embedded in the fractured vault at the end of the track, the only injury of the brain being a linear bruise on the mesial aspect of each frontal lobe along the course taken by the bullet. The mucous membrane of the palate was blackened by smoke behind the wound. The front of the chin had been injured, probably by the kick of the revolver, and the lips were bruised and slightly lacerated from the sudden escape of gases at the moment of discharge. Asphyxia was the cause of death, blood having run from the nose into the air passages as he lay unconscious.

This was more probably a suicidal act, though it is just possible that he was imitating a suicide, not suspecting that the revolver was loaded. From the slight amount of injury of the brain by the bullet it is possible that he retained consciousness long enough to

enable him to place the revolver in the drawer, at some distance from the spot where he was found, and to close the drawer afterwards.

A Reconstruction of a Murder.

The best example in my experience of the reconstruction of a murder was that of a soldier in camp at Aldershot, who was found dead in a hut at night, shortly after the sound of a shot had been heard. The other occupant of the hut, a soldier, was afterwards charged with murder. The death was at first thought to be a suicide, the coroner was informed; an inquest was held without a post-mortem examination and a verdict of suicide was recorded, the body then being buried. Several suspicious circumstances, however, led to the arrest of the other occupant of the hut, and at the time of my investigation he was awaiting his trial at the assizes.

When he was discovered the dead man was lying on his back, covered with bed-clothes up to the chest, and clothed in underwear and socks; his face, turned to the right, was at the edge of the bed. There was a bullet wound on the left cheek immediately below the malar bone which was not fractured, and the characters of the wound and the changes around it were carefully noted by the medical officer. On turning the head the exit wound was found immediately behind the right mastoid process. The weapon, a service rifle, was on the floor close to the bed and between the outstretched arms of the dead man, but was not grasped, nor were the hands blackened. The cartridge was a Mark 303. After leaving the head the bullet traversed the bedding and a pillow consisting of a bag containing uniform, and an examination of these showed that no metal or other hard object had been struck; the bullet had then passed through the wall of the hut, constructed of two layers of three-ply wood with a space between. In this part of its course the trajectory formed an angle of 35° with the horizontal; it had undergone no deflection in its passage through the wall, and a furrow produced by its striking the path outside was in the same line.

On plotting out upon a skull the line joining the entrance and exit wounds it was found to cross the central nervous system at the junction of brain and spinal cord; the passage of the bullet must have resulted in instant paralysis, and probably instant death. To bring the track of the bullet through the head into line with the track in the wall the head must have been resting on the pillow in a half lateral position when the weapon was fired, and must have rolled completely to the right immediately afterwards. The weapon must have been pointed in a downward direction at an angle of 35° .

To ascertain its distance from the head experiments were made with the weapon, using cartridges of the same pattern, and the blackening seen around the wound in the cheek was found to correspond with a muzzle distance of more than 2 in., and probably about 5 in. The weapon was $3\frac{1}{2}$ ft. long from muzzle to trigger. The dead man was 5 ft. $7\frac{1}{2}$ in. in height; and it was impossible for a man of that height to have touched the trigger with his finger, with the muzzle 2 in. from his cheek, when lying in bed. The weapon could not have been discharged by his foot, as paralysis would have prevented him from replacing his foot beneath the bed-clothes after the weapon was discharged. The wound, therefore, could not have been self-inflicted, and the prisoner was the only other person who was in the hut at the time. He was found guilty.

Bullet Wound of the Abdomen.

The only bullet wound of the abdomen in my series was a suicidal injury by a middle-aged woman who shot herself with a revolver, the entrance wound being $1\frac{1}{2}$ in. below the ensiform cartilage.

The weapon had probably been pressed against the abdominal wall, the skin around the bullet wound being scorched, but not blackened or tattooed. Both these changes, however, were found on dissection upon the front surface of the anterior sheath of the rectus muscle, which had been separated from the superficial tissues for some distance round the track. The bullet passed directly backwards and was found beneath the skin in the middle line of the back at the same level; it had passed through the left lobe of the liver and the upper part of the stomach close to the pylorus, producing only one opening in the mucous membrane; these wounds had been sewn up. The bullet then passed through the head of the pancreas, dividing the pancreatic duct, between the abdominal aorta and the vena cava, without injuring either vessel; it then traversed the body of the first lumbar vertebra, crossing the spinal canal without injuring the cord or its membranes.

This is a good example of the passing of a bullet between yielding structures such as blood-vessels without injury.

Bullet Wounds of the Chest.

In every case in the series of suicidal wounds of the chest the entrance wound was situated in the upper part of the front of the left chest in the area between the sternum and the vertical nipple line. The weapon in several of the cases was fired through the clothing, suicidal injuries by firearms differing in this respect from incised wounds and stabs. In these cases the bullet passed directly backwards, deviating but little from the horizontal, and only slightly to one side or the other; the left lung, the heart, the aorta, and the pulmonary artery being damaged by bullets.

One suicidal injury was produced by a shot-gun. The entrance wound was a single opening, circular, and only slightly larger than those produced by a bullet, with a ring of blackening around its margin, but a large hole had been blown in the chest wall, three ribs were smashed, one comminuted, and the heart wall, excepting the right auricle, was torn and the muscle was in strips; the descending thoracic aorta was shredded for a distance of about 3 in. None of the pellets had left the body. This injury was quite unlike a bullet wound when its course in the chest was examined.

Homicide by Firearms.

In cases of homicide by firearms multiple injuries are more frequent than in suicides. If an injury in a vital area is associated with one in the hand or arm it is a strong presumption of homicide. The two injuries may have been caused by one bullet, the arm having been raised to cover the body, and in such a case the arm can be placed in a position so that the two wounds come into the same line. Injuries in the limbs may be produced by the rapid emptying of a revolver, some of the bullets missing their main objective. An injury such as one passing through the calf of the leg from behind, forwards and downwards, associated with a wound in a vital area is strong evidence in favour of homicide.

In homicidal cases the distinction of wounds of entry and of exit is often a matter of considerable difficulty, especially when the weapon is a service revolver or a modern rifle. Discharged at a range of more than five or six feet from the body, there will probably be no mark on the clothing or skin around the wound to indicate the wound of entry, and in size and shape the two wounds may be very similar, especially with the more pointed type of bullet, though the exit wound tends to be more slit-like, and the entrance wound circular. It may be impossible by examination of the injuries to say in which direction a bullet has traversed the body, but when an examination is made before the body is moved, or the clothing disturbed, a bullet may be found lodged against a metal object in the clothing, such as a watch or spectacle case, lying between that object and the exit wound on the body. I have had cases in which valuable information has been lost by failure to search for bullets in the clothing when the body was first inspected, the bullets afterwards falling from the clothing during removal, or during the stripping of the body for post-mortem examination. Homicidal bullet wounds in the chest are only situated in the area usual in suicides in a small proportion of cases.

In one case a husband shot his wife with a service revolver when he was in bed with her. The wound both in position and direction through the chest was indistinguishable from a suicidal injury.

In another case a bullet had entered within the suicidal area, passing backwards and slightly to the right, opening the arch of the aorta; another wound below and to the outside of this one had passed very obliquely across the chest, from left to right and slightly backwards, traversing the apex of the heart, opening the left ventricle, and passing through the right lung. A wound in the left upper arm could be brought into line with this injury. Another bullet had passed through the neck from before backwards, another through the head, from forehead to occiput, completely destroying the upper part of the pons, whilst yet another through the right forearm could not be placed in line with any

of the other injuries. This man had therefore been struck by at least five bullets, and apart from the distinctive characters of the wounds on the arms the three vital injuries through the heart, aorta, and brain placed its homicidal causation beyond doubt.

In other cases of homicidal chest injury the site of the entrance wound and the direction taken by the bullet were such as to make it very difficult, if not impossible, for the injury to have been self-inflicted.

In one case the bullet entered the upper part of the front of the left chest and ran very obliquely downwards and to the right at an angle of 45°, traversing the left lung and the descending thoracic aorta.

In another case where the entrance wound was on the upper part of the front of the right chest wall the wound ran so obliquely to the left that it could have been self-inflicted only with difficulty with the weapon, a revolver, held in the right hand, whilst another wound passing through the inner part of the right upper arm could only have been self-inflicted with the left hand. In this case the victim was in bed when the shots were fired, and several other bullets fired at the same time were embedded in two adjacent walls. The trajectory of these bullets, judged by their tracks in the wall, showed that they had all been fired from a position in the centre of the room about 4 feet from the bed, and they could not all have been fired by the person in bed. The absence of tattooing and blackening on the pyjama suit and on the skin about the entrance wounds also established that the weapon had been discharged more than 3 feet away.

In another case the bullet entered high up in the right axilla, smashing the fourth rib, crossing the right lung at its root, passing through the descending thoracic aorta, and traversing both lobes of the left lung. Fragments of bone from the smashed right rib had been carried through the right lung and aorta, and were deposited in the track of the bullet in the left lung. The bullet had then smashed the left fifth rib and left the body at the back of the left shoulder, where there were three small wounds close together, one produced by the bullet and the other two by fragments of bone.

In another case in which the victim was shot whilst entering his house, two persons were charged with murder, each being in possession of a revolver. The assailants stood some distance away and on opposite sides of the house, and the question might have been raised at the trial whether the fatal injuries might have been caused by one only of the assailants. Five bullet wounds were found in different parts of the body, one of which had entered the left axilla, crossed the upper part of both lungs, and was found embedded in the head of the right humerus, and a second bullet entered in the right axilla, traversed both lungs at a slightly lower level, and was found lodged in the left axilla. These two fatal injuries were inflicted from opposite sides, and both assailants were equally implicated in the death.

Another homicidal injury afforded a proof of the ease with which a bullet may have its course in the body altered.

A woman was shot from above as she ran downstairs, two bullets passing through her chest. One of these entered on the front of the left shoulder, where slight scorching and blackening and a little tattooing of the surrounding skin showed that the weapon had been fired at short range. The bullet passed downwards and to the right, just missing the anterior border of the left lung, ploughing a furrow across the front of the heart, which opened into the right ventricle; the bullet then penetrated the right chest wall and was found under the skin. The penetrative power of this bullet was insufficient to carry it completely through the body, although it had struck no bone in its course. The second bullet entered the front of the right chest immediately internal to the nipple; there were no marks on the skin around, and this injury was probably inflicted after the other. The bullet passed downwards and somewhat inwards, and struck the upper border of the fifth right costal cartilage. The cartilage had been crushed and softened at the point of impact. From this point the bullet had rebounded very much like a billiard ball from the cushion, and its course was then upwards, backwards, and to the left, bruising the anterior border of the right lung, traversing both ventricles of the heart, and crossing the upper lobe of the left lung, to leave the body at the back of the left shoulder. The two bullets, although their direction when they entered the body was at right angles to one another, had taken such closely parallel courses in the chest as to render it a difficult matter to follow their separate courses. The assailant then shot himself with the same weapon, which was a short-barrelled revolver of small bore.

One other case is an example of an unusual complication of a bullet wound in the lung.

A girl was shot in the street, the bullet entering at the back of the left chest 1½ in. from the middle line. It traversed the left lung, passing through both lobes. She was admitted into hospital in a state of collapse; a large quantity of blood was removed from the left pleural cavity, but she died 24 hours after admission. At the post-mortem examination another collection of blood was present in the pleural cavity; in the lower third of the ileum there were six areas of early gangrene of the bowel wall with peritonitis over them; nothing was found locally to account for the gangrene. On opening the heart, however, the left auricle contained a clot spherical in shape and about the size of a marble, which was unattached and floated when placed in water. When it was incised it consisted of a thin layer of blood-clot enclosing a cavity filled with air. The air had reached the auricle from the wound in the lung, and the gangrene of the intestine was presumably the result of air embolism.

Finally, only two of my cases of bullet wounds were undoubted accidents.

In one of these a man was shot by a friend who was examining a revolver, not knowing it was loaded. The bullet entered the neck in front, immediately to the right of the larynx, crossed the oesophagus, and passed through the body of the sixth cervical vertebra and through the spinal cord. The victim fell to the ground and was found to be paralysed, dying some hours later.

In the other case a trooper was shot by a comrade whom he was teaching to fire a Colt's revolver, the weapon being presumed to be unloaded. The bullet had entered the front of the left chest in the area common in suicidal cases, and had taken a course somewhat similar to that of suicidal injuries, backwards and somewhat to the right. It passed through the right ventricle, aorta, and left auricle, in addition to the two lungs. Unconsciousness supervened in a few seconds.

RUPTURE AND AVULSION OF THE UTERUS AT THE TIME OF LABOUR.

CASES WHICH RECOVERED WITHOUT OPERATION.

By HERBERT R. SPENCER, M.D., B.S.,
F.R.C.P. LOND.,

OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

RUPTURE and avulsion of the uterus at the time of labour is a very rare accident. A recent case of the kind in which the medical man in attendance was convicted of manslaughter—the conviction being happily quashed by the Court of Appeal—raises questions of great importance and concern to medical men who practise midwifery, and especially those who are called in by midwives, as regards their responsibility for the rupture, for the avulsion, and for the subsequent treatment.

With regard to the rupture it is well known to obstetricians that the uterus or vagina may rupture spontaneously even in cases with normal pelves and apparently normal tissues. (I have seen two cases.) The vagina is a fragile tube which I have known to be ruptured in four cases during the act of coitus. The uterine (or vaginal) laceration, once started, is very easily extended; this may be demonstrated during Cæsarean section, where, as in certain cases of fibroids or cancer, it is necessary to remove the uterus. The safest way to deliver the child in such cases, particularly if the membranes are ruptured, is to make a small hole and tear the uterus open. This is done rapidly and with surprising ease by two flips of the forefingers, so to speak. Version in cases of shoulder presentation and the use of forceps before the cervix is sufficiently dilated are two of the commoner causes of these ruptures, which often extend so as to separate the bladder and tear the ligaments. In such cases the avulsion of the uterus would not require much force.

With regard to the mistaking of the edge of the rupture in the uterus for the edge of the placenta, the late Dr. Galabin, one of the most experienced and skilful of British obstetricians, has recorded a case where he temporarily made this mistake.¹

¹ Obs. Soc. Trans., vol. xx., 299.

With regard to treatment, the patient with rupture of the uterus is usually suffering severely from shock and hæmorrhage; in cases of avulsion of the uterus probably always so. In such cases, to move the patient would be almost certainly fatal. No operation is required to restore the pelvic floor. Removing clots from the vagina, washing out the abdomen with salt solution, and the application of a pack of iodoform gauze to be left in situ for a few days would seem to be the best local treatment for these terrible cases. I have successfully applied it in two cases of complete rupture of the uterus.² That patients kept absolutely at rest, without operation, can recover after avulsion of the uterus is shown by the following records.

The first account of this occurrence which I have been able to find is that published by Wrisberg in 1800. The case is admirably described in detail with the name of the doctor (Hepe) who called Wrisberg into consultation, of the midwife (Rippel), and the patient (Ude), who lived in Reyherhausen. The account is in Latin, and as it has features of interest in connexion with the recent occurrence of the same kind in this country, a brief translation may be given.

Wrisberg's Case ("Commentationes," 1800, vol. i., p. 435).—The patient, a primipara, aged 24, felt the first pains of labour at 7 o'clock in the morning of June 5th, 1780. Her pregnancy had run its proper course without any symptoms except sadness at the absence of her husband, who was then fighting with the Hessian forces in America.³ The pains gradually became stronger and more effective, and between 2 and 3 o'clock in the afternoon, after a perfectly natural labour, the patient brought into the world a living well-made girl.

Having placed the infant in its cot, the midwife returned to the patient, and when asked to loosen and extract the after-birth she tortured the patient with such vigorous, zealous, and repeated manipulations (introducing her arm into the uterus) that the patient fainted, and when she saw a large mass of flesh hanging from the vulva she was only able to pronounce the words "Oh! you're tearing everything out of my body," and felt she would surely die. So severe was the pain that she cried out, and there is no doubt (says Dr. Hepe) that the midwife then cut away the inverted uterus, which, with the placenta which she had peeled off, she placed in a vessel and shortly afterwards buried.

The woman lay for two days without any care or treatment directed either towards stopping the bleeding or saving and comforting the patient, who was abandoned to the "beneficent and curative efforts of Nature." The very severe flow of blood which followed the amputation of the womb and ran down like a torrent into the room spontaneously ceased under the influence of the profound fainting, which so affected the poor woman that she seemed almost dead. Two days later, on June 7th, she asked in a very feeble voice that Dr. Hepe should be called in, who found the patient in the following condition:—

The colour of the face was very pale, just like that of a dead woman; the extremities—the brow, nose, ears, hands, and feet—were cold to the touch; the countenance that of a dying woman, the eyes dull and heavy; the voice very weak, scarcely perceptible. The pulse was almost absent and could only be felt in the large arteries; the respiration short and shallow, and the movement of the thorax scarcely to be felt. Up to this time (the second day) the patient had neither desired nor taken any food. Wrisberg was called in consultation and saw the patient on June 8th (the third day). He removed clots, mucus, and pus from the vagina and found that the gap at the top of the vagina was almost closed by the full bladder. Having passed a catheter he was able to examine more thoroughly. Scybala could be felt in the rectum, and in the gap at the top of the vagina

(which had contracted to the size of the diameter of the thumb) he felt a softish, slippery body, which he took for a coil of intestine. "It goes without saying," he writes, "that I was very cautious lest, moved by much curiosity, I should pass my finger too high and hinder the effort of Nature to close the gap, or by too much irritation and handling of the vessels should cause a return of the hæmorrhage." He was able to observe that the canal of the vagina became narrowed like a funnel towards the gap. There was an unpleasant odour like that of gangrene from the vaginal discharge.

Wrisberg prescribed "Summa corporis animique quies"; a moistened sponge was inserted into the vagina to prevent prolapse of the intestines, suitable injections (justæ injectiones) were ordered to wash away the discharge, and mineral acids were administered. On June 16th the patient was able to get out of bed and walk about, and later was shown by Wrisberg with her baby and the uterus to his obstetric colleagues. She made a complete recovery, and on the return of her husband from America she resumed conjugal relations, but stated "Se non amplius voluptatis sensum percipere quem alias percepit."

Bernhard's Case (v. Siebold's "Lucina," vol. i., p. 401).—In this case inversion of the uterus was caused by a forcible removal of the placenta by a midwife who mistook the uterus for a tumour and cut it away with a razor. Ice was inserted into the vagina to stop the bleeding. The patient fainted. There is no mention of a tampon being inserted. The patient recovered "simply by rest and milk diet, without any medicine." When examined later by Bernhard a rectocele was found. The vagina had healed. The patient looked well.

Breslau's Case ("De totius uteri exstirpatione," Inaug. Diss., Munich, 1852).—The patient was 39 years of age, strong and healthy. She had had two children previously, one of which was born dead, apparently as a result of a fall. On Jan. 9th, 1850, at 1.30 p.m., she was delivered of a living well-developed girl. She was attended by a midwife. The labour only lasted an hour and a half. The placenta remained in the uterus, but there was no bleeding. The midwife endeavoured to remove the placenta by introducing her right hand into the uterus and by pulling with the left hand on the cord, which broke. In spite of all her endeavours she was unable to remove the placenta, and at 7 p.m., telling the friends to send for a doctor, she left the patient and went off to another case. The doctor arrived at 9 p.m. and found the patient pale, with cold extremities and small pulse, clots in the vagina, and copious hæmorrhage still going on. The doctor removed the clots, passed his left hand into the vagina, felt the torn end of the cord high up, and some membranes. Using these as a guide, he passed his hand (as he thought) into the uterus, made a couple of "supination movements" to get the hand behind the "placenta," and felt a large body around which he could move his hand without feeling any adhesions to speak of. On account of its size he was in doubt whether this was the placenta, and thinking it was a mole which could not pass, he seized it in the hollow of his hand and, pressing from above (with the other hand), he separated a few adhesions with his finger and nail, and delivered it. To his surprise he found it was the uterus (with its appendages) attached only to the vagina at a few points, which he severed. Overcome with despair, he left the patient to her fate. Next day she was seen by another doctor who prescribed medicine, strict diet, and rest. She gradually recovered, though a fæcal fistula persisted for six months, but finally closed.

The doctor stated that he had removed the uterus without using any force ("ganz ohne Gewalt"). He was punished with some months of imprisonment and suspension from practice. The midwife received no punishment, although "she had probably already prepared the best way" for the removal of the uterus.

Nieprasch's Case (Berliner klin. Wochenschr., 1880, p. 388).—The case was that of a woman, aged 29, with

² Ibid., vol. xlii., 14.

³ In the War of Independence. The capture of a Hessian detachment at Trenton in December, 1776, is said to have been the turning point of the war (Chambers's Encycl.).

a normal pelvis, the mother of seven children, three of whom had been delivered with the aid of the doctor owing to abnormal presentations. In the labour at which the rupture occurred the child also presented abnormally (by the feet). Severe hæmorrhage occurred and signs of extreme anæmia. The uterus (with the head in it) had been torn away by the midwife and lay in the bed, held only by one round ligament. The patient was seen by the doctor two hours after the delivery. Small intestines had prolapsed; these were replaced and a sponge was inserted into the vagina. The patient recovered.

Credé's Case.—No particulars are given; the only record being the statement by Nieprasch that "Prof. Credé had told him of a similar case."

E. Schwarz's Case (*Archiv für Gyn.*, 1880, p. 107).—The patient, aged 29, had had eight children (two born dead in head presentation) and was delivered easily and quickly of her ninth child, a feeble girl, which presented by the head and was born alive. The cord had been pulled upon by the midwife and broke. The placenta was removed by hand. As the midwife thought a piece had been left behind she introduced her hand a second time, when she felt what she thought was a tumour, which she tore away. The doctor who was called also thought it was a tumour till he found it was hollow and had the adnexa upon it. The bleeding had stopped. Clots and intestines were felt in the upper part of the vagina. The clots were removed and a tampon of clean linen inserted into the vagina. Absolute rest and wine and salicylic acid were ordered. The recovery was complete. The midwife was fined and deprived of her licence.

J. C. Cooke's Case (*THE LANCET*, Jan. 16th, 1836).—The patient, an Irishwoman, was delivered by a midwife in the knee-elbow position after a very painful labour lasting 48 hours. The placenta followed naturally. Free hæmorrhage and strong after-pains ensued, and during micturition the uterus appeared to have become inverted, with increase of the bleeding and the pains. On being called to the patient 36 hours later the midwife found a mass as large as a child's head lying between the patient's thighs, loosely connected to the vagina by a shred of membrane only. It was removed without effort and placed in a bowl. The hæmorrhage then ceased. The doctor, on examination, found the mass removed was the inverted uterus. No internal examination was made. Perfect quietude, absolute rest in the horizontal position, and a light farinaceous diet were ordered. No active medicine was given. The patient made a good recovery.

CANCER AND HEREDITY.

By P. LOCKHART-MUMMERY, F.R.C.S. ENG.,
SENIOR SURGEON TO ST. MARK'S HOSPITAL FOR DISEASES
OF THE RECTUM.

It has often been asserted that cancer is not an hereditary disease, and this statement is probably correct; indeed, we know of very few hereditary diseases, but it does not follow that a predisposition to cancer may not be transmissible by heredity. Anyone who has taken the trouble to study Miss Maud Slye's work on natural cancer in mice¹ must have been struck by the very remarkable results which she has brought forward. These certainly seem to show that there are definite predisposing causes transmitted by heredity which tend to cause mice to die from cancer in succeeding generations.

The relationship between heredity and disease is one of the most interesting, and at the same time one of the most difficult problems of modern medicine. The causes at work are very obscure, and the laws governing heredity are but imperfectly understood, though no one can doubt that hereditary predisposition to disease is a most important factor; indeed, it is so recognised by the insurance companies. The study

of heredity in human beings is beset with difficulties which are almost insuperable. Human life being relatively long, and in any case being much the same as that of the person who desires to trace it, the latter is obliged to rely upon records. Three generations cover a period of nearly 100 years, and there are seldom accurate or reliable figures available even as far back as this. Now three generations are not enough; at least ten generations are, as a rule, required to establish an hereditary factor with any degree of accuracy. The following facts, therefore, are offered for what they are worth, and although I should be far from wishing to maintain that they prove anything, I think they suggest a very important addition to our knowledge of the ætiology of cancer.

Clinical and Family Records.

CASE 1.—A young woman, aged 31, came into my ward at St. Mark's Hospital with multiple polypi of the colon. Examination showed that she had a vast number of simple adenomatous polypi throughout the visible part of the rectum and colon, when examined with the sigmoidoscope. I removed her colon, as the only feasible means of relieving her, and she made a good recovery. The colon removed was found to be studded with adenomata as far as the ascending colon.

I was already aware that this condition of multiple adenomata was invariably antecedent to carcinoma, one or more of the adenomata sooner or later undergoing malignant change. I also knew that the condition of multiple adenomata is often hereditary in a marked degree, and with this in view I asked my house surgeon, Mr. J. C. Anderson, to make careful inquiries into this patient's family history, and as a result the following extraordinary family history was obtained.

The patient is one of a family of four, and on her mother's side had nine uncles and aunts. Seven of these, including her mother, have died of cancer of the bowel at ages between

CHART 1.—Family History of Case 1.

In each chart cases indicated in black had either cancer or multiple adenomatosis of the bowel, or both.

30 and 54, and her maternal grandfather also died of cancer of the bowel. In order to verify this remarkable history I wrote to the doctors said to have been attending these relatives, or to the registrars of the districts where they were supposed to have died. Although I was not able to trace all, which one could hardly expect since they were much scattered and have died over a period of 20 years, I was able to trace several, and to find confirmatory evidence of their having died of cancer of the bowel. Also another relative, one of the cousins of my patient, subsequently consulted me and was able to confirm the facts as I already had them. I was also able to confirm the fact that the grandfather died of cancer of the rectum. As far as such things can be verified, therefore, the facts as given by the patient as to her family history are correct.

Several facts are noticeable. The large proportion of individuals in a single family that have died of cancer of the bowel is remarkable, also the comparatively early age at which they developed the disease, no less than seven having died between the ages of 27 and 54. Although it cannot be proved, I have very little doubt that all these persons inherited the tendency to the development of multiple adenomata of the large bowel, and that the cancer which caused their death was a secondary process.

I next started to inquire more closely into the family history of two other patients, whom I had had under my care with the same condition, with the result that the following histories were obtained.

CASE 2.—The patient was a young woman, aged 22, who came to the hospital with a history of diarrhoea and bleeding of two and a half years' standing. Examination revealed an

¹ Jour. of Cancer Research, April, 1922, vol. vii., No. 2.

extreme degree of multiple adenomatosis of the entire large bowel. I performed a complete colectomy, and subsequently removed the adenomata in her rectum. She has been kept under observation for the last four years, and on two occasions has had adenomata which had recurred removed.

CHART 2.—Family History of Case 2.

The brother of this patient was treated in St. Mark's Hospital for multiple adenomata of the rectum and colon in 1913, and he died from cancer of the rectum in another hospital in 1919 at the age of 36. The patient's father died from cancer of the sigmoid flexure in St. Bartholomew's Hospital, and several of his brothers and sisters are said to have died from cancer of the bowel. Both the grandfather and grandmother are said to have died from cancer of the bowel.

CASE 3.—The patient is a girl, aged 20, and is now under my care at St. Mark's Hospital with multiple adenomatosis of the large bowel. Her brother also has multiple adenomatosis and has been under my observation since he was 11 years

CHART 3.—Family History of Case 3.

old; he is now 26. Numerous polypi have been removed from his bowel on different occasions. This patient's father died from cancer of the rectum in St. Mark's Hospital in 1922 at the age of 46. The grandfather's brother died of cancer of the rectum, and the grandfather on the mother's side died of cancer of the throat at the age of 50.

It is noticeable that in both these cases also there is evidence of the condition being markedly hereditary, and that the deaths have always been from cancer of the large bowel. In the case of the brother of Case 2, he was in St. Mark's Hospital with multiple polypi in 1913, and died from cancer of the rectum in another hospital six years later. In this case the actual proof exists that the patient had multiple adenomata and died of cancer. Multiple adenomatosis of the large bowel is admittedly a rare disease, but it is often by the study of extreme cases that one is best able to throw light on the more common condition.

Tendency of Adenomata to Malignant Change.

The conclusion which, it seems to me, can be drawn from these cases is that cancer of a particular part of the alimentary tract may cause the death of a large proportion of the members of one family in succeeding generations, the hereditary factor being not cancer itself, but simple tumours (multiple adenomata) having a marked tendency to undergo malignant change. This conclusion, if correct—and it would seem to be justified by these three family histories—is of considerable importance. We have for some time known that a simple adenoma of the rectum is often the forerunner of a cancerous growth. A simple adenoma has a marked tendency in time to undergo malignant change which eventually involves the whole tumour. I have on several occasions seen this occur. A few years ago I removed a simple adenoma from

the anterior wall of a patient's rectum and warned him of the necessity of being kept under observation. This, however, he neglected to do, and I did not see him again for a little over a year. I then found he had a typical carcinoma in the position of the scar, where I had removed the adenoma. Further, a careful examination of specimens of cancer of the rectum show that in quite a number, part of the tumour is a simple non-malignant adenoma, though the remainder may be typical adeno-carcinoma, and, still further, that simple adenomata are frequently to be found growing from the mucous membrane of the bowel either above or below the position of a cancerous tumour. There is no doubt that while some adenomata remain innocent tumours for long periods—I have had some under observation for periods as long as seven years—others undergo malignant change very quickly. In cases of multiple adenomata the tendency to undergo malignant change is so pronounced that I have never known a patient with this condition who did not develop cancer. One cannot help wondering what proportion of cancers of the rectum and colon start as simple adenomata, and even whether it may not be possible that in all cases a simple adenoma is the starting-point of a cancerous growth.

Sir Lenthal Cheatele has demonstrated that duct cancer of the breast is often preceded by multiple duct adenoma, so that we have evidence of a similar sequence of events in the case of breast cancer.²

The Hereditary Predisposing Factor.

The hereditary factor of cancer would from this limited investigation appear to be quite indirect. Although at first sight the history in these three families would seem to prove that cancer of the bowel had been transmitted, such is almost certainly not the case; another factor has been transmitted by heredity which has predisposed the descendants to the development of cancer. Tubercle from a study of family history alone would appear to be an hereditary disease, but we know it is not. It is some predisposing factor which is hereditary in the case of tubercle, and the same is probably true of cancer.

Miss Maud Slye has shown in respect of mice that a predisposition to develop cancer is definitely hereditary in these rodents. That mice bred from cancer mice will tend to develop cancer, and further, that they will tend to develop cancer of the same organ as the ancestors. She has further shown that the predisposition to develop cancer is recessive, and that the tendency not to develop cancer is dominant. So that by breeding a strain of non-cancer mice to a strain of cancer mice the development of cancer in the succeeding generation can be held off for as much as nine generations, but will show itself as soon as two heterozygous mice are bred together.

We have got to ascertain what the predisposing factors are in mice. I think the facts here produced point to one of the predisposing hereditary factors of cancer of the rectum in human beings. Even though multiple adenomatosis is a rare condition, it would appear to be of importance and well worth further investigation. Like all investigations into the causes of cancer this, while it possibly proves one more link in the chain of our knowledge, only leaves us with fresh questions requiring an answer.

Questions for Solution.

What is the nature of the transition from a simple to a malignant tumour of the mucous membrane, and what are the factors causing it? This we are now attempting to investigate in the research department of St. Mark's Hospital. A much more important question is: What are the causes of the development of simple adenomatous tumours? For an adenoma is in its way just as abnormal a development on normal mucous membrane as is adeno-carcinoma. It would seem that research into the origin of simple epithelial tumours might be more fruitful of result than the investigation of malignant tumours themselves, and

² Brit. Jour. Surg., 1923, vol. x., No. 40; also Brit. Med. Jour., April 12th, 1924.

this is certainly a branch of research which has been neglected.

Conclusion.

1. Adenomatosis of the large bowel is a condition which tends to develop in succeeding generations in the same family.

2. Individuals with multiple adenomata of the large bowel almost invariably develop cancer in one or more of the adenomata after a few years.

3. The members of families with an hereditary tendency to multiple adenomata tend to die of cancer of the large bowel, and at an early age.

4. Simple adenomata of the large bowel are a common antecedent of cancer.

THE ORAL ADMINISTRATION OF LARGE QUANTITIES OF GLUCOSE,

AND ITS THERAPEUTIC USES.

By T. IZOD BENNETT, M.D., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN AND ASSISTANT TO THE PROFESSOR
OF PHYSIOLOGY, MIDDLESEX HOSPITAL;

AND

E. C. DODDS, M.B., B.S., B.Sc. LOND.,
LECTURER IN BIOCHEMISTRY AND CHEMICAL PATHOLOGIST
TO THE HOSPITAL.

(From the Department of Physiology and the Biochemical
Department of the Bland-Sutton Institute of
Pathology, Middlesex Hospital.)

THE primary object of this inquiry was to determine the therapeutic value of glucose administered orally. Impressed by the physical transformation often produced in severe cases of diabetes mellitus when treated with insulin, it seemed to us probable that a somewhat equivalent improvement in nutrition should be obtainable in many non-diabetic patients suffering from diseases associated with wasting, provided that either (a) glucose could be administered in really large quantities, without marked loss in the urine, or (b) this glucose administration was accompanied by insulin administration.

Method of Preparing Glucose for Administration.

Pure glucose, whether crystalline or anhydrous, is expensive, costing about 8s. 6d. per lb. It is little used save in chemical laboratories. There is on the market a preparation known as "glucose B.P." hereinafter referred to as "commercial glucose," which can readily be obtained in jars containing 1 lb. or more at a cost of about 6d. per lb. On account of its cheapness, this is clearly the best preparation readily available for clinical use on any extensive scale. Notes on its chemical nature will be found in a succeeding section. The easiest method of preparing it in palatable form is to dissolve it in water with a plentiful addition of fresh lemon-juice.

The formula we employ is as follows: Commercial glucose, 1 lb.; water, 1 quart; lemons, two. The glucose is dissolved by stirring into the boiling water, the lemons are squeezed into the solution, then cut in quarters, boiled with it for a few minutes, after which the solution is cooled and strained. A patient will drink daily upwards of a pound of glucose so prepared, in small drinks between or with meals. We have never encountered difficulty or complaint concerning it.

For experimental purposes we have used a similar but more exact formula: Commercial glucose, 1 lb. (i.e., 450 g.); water, about a pint; lemons, two. A solution is made as before, and, after cooling and straining, its total volume is made up to 900 c.cm., so that the final solution contains 1 g. of commercial glucose in every 2 c.cm. of fluid. Stronger solutions than this are syrupy and cannot be drunk readily, but this is only slightly stronger than the average home-made lemonade.

Nature of Commercial Glucose.

Glucose B.P. is a viscid syrup, prepared by the hydrolysis of Indian corn or other cereal starch with mineral acids. It appears that hydrochloric acid is now usually employed for this purpose, but some years ago sulphuric acid was generally used. Contamination of this acid with arsenic resulted in several epidemics of arsenical poisoning, with the result that the use of the commercial product in jams, &c., fell into great discredit. Such foods are to-day frequently

labelled "guaranteed free from glucose." Glucose B.P. is guaranteed to contain less than two parts per million of arsenic, so that 42½ lb. of it would have to be taken before a patient could receive 1 gr. of arsenic. We have tested a number of samples from various sources, and Marsh's test for arsenic was negative in every case.

The exact chemical composition of commercial glucose is very difficult to determine; it consists of a mixture of dextrins, glucose, and maltose, all of which are dextro-rotatory, the two latter reduce copper solutions, and the determination of the precise proportions of them in a given sample is a matter of the greatest difficulty to the analyst. All of these substances are readily hydrolysed to glucose by acid or the amylolytic enzymes of the digestive juices, with the exception of achroödextrin, which is stated to be less easily digested and not readily absorbed from the alimentary canal. The proportion of water present in glucose B.P. makes it necessarily weaker than crystalline or anhydrous glucose; the additional water appears to account for about 10 per cent. of the weight in any given sample.

The difficulty of precise analysis, and the varying amounts of water and of achroödextrin present, make it impossible to give exact figures as to the calorie-value of commercial glucose. It must be remembered that close inquiry reveals equal difficulty in determining the true calorie-value of almost every known class of food-stuff. Taking the calorie-value of the various carbohydrates present to be not less than 3.7 large calories per gramme, and allowing 60 per cent. as a conservative estimate of the amount of assimilable carbohydrate in average samples, we may assume that 1 lb. of commercial glucose will yield 1000 large calories when taken as a food. Dissolved in a minimum quantity of water it forms a strong syrup, and when diluted to the strength we use for clinical and experimental purposes, it is still a solution of very high osmotic pressure.

A most important difference between this substance and cane-sugar is that it is relatively less sweet; this is a property of considerable value, as it enables quantities to be taken greatly in excess of what can be accomplished with ordinary sugar.

PHYSIOLOGICAL EXPERIMENTS.

Clinical observation of cases when strong glucose solutions were being administered taught us that glycosuria following its use was a comparatively unimportant phenomenon. We had shared what we believe to be a very widespread opinion—namely, that glucose, when taken in a single dose exceeding about 150 g., will cause glycosuria in normal people, an amount roughly approximating to the excess over this figure being excreted by the urine. Medical literature abounds in reference to sugar-tolerance, but such references are almost entirely confined to observations upon diabetic subjects or those with various disorders of carbohydrate metabolism. Work on the upward limit of normals is sparse, and appears to have been largely confined to a few observations in which the oral dose of glucose had been determined by the appetite of the observer. From this erroneous deductions have been drawn. Even such an authority as F. M. Allen says,¹ "250 g. (of pure dextrose by mouth) may probably be considered as the upper normal limit," and, again, "the human tolerance by mouth must be figured as probably between 2 and 4 g. per kilo., with possible slight variations in either direction."

TABLE I.—To Show Degree of Glycosuria Produced by Administration of Large Doses of Glucose by Mouth.

Subject.	C.G. taken.	S.E. in urine.	Subject.	C.G. taken.	S.E. in urine.
1	200	0.37	9	200	Nil.
2	200	Nil.	10	200	Nil.
3	200	Nil.	11	250	Nil.
4	200	Nil.	12	250	Nil.
5	200	Nil.	13	300	Trace.
6	200	0.12	14	300	Nil.
7	200	Nil.	15	300	0.16
8	200	0.65			

C.G., Commercial glucose.

S.E., Sugar excreted.

To test the amount of sugar-loss likely to occur, after giving a single concentrated dose of glucose we administered ½ lb. or more to a number of healthy men, students and laboratory workers; the solution being that described in an earlier paragraph. Typical results are given in Table I.

It is clear from these results that, though these large doses may induce the passage of a trace of sugar into the urine, no appreciable loss occurs, the total amount of sugar excreted in the urine collected from 15 experiments in which from 200–500 g. of commercial glucose were taken by each subject only amounting to 1·3 g. This result agrees with those published by Taylor and Hulton,² who found that amounts of 500 g. of pure glucose given by mouth often produced no glycosuria and never a considerable passage of glucose into urine. Similar results are indicated by the work of Woodyatt, Sansum, and Wilder.³

In view of the current belief that the organism has definite limitations as to its capacity for metabolising large amounts of ingested sugar, these results are surprising, and immediately provoke inquiry as to the mechanism by which glucose is dealt with. With a view to gaining clearer knowledge on the problems concerning the fate of this glucose, we made closer investigations of those cases in whom a dose of 500 g. had been taken. The results of these more minute inquiries are as follows:—

(a) *Effects on the Amount and Quality of Urine Passed.*—The subjects were all observed in the morning: they were at that time fasting, urine was passed until the bladder was emptied, 500 g. of commercial glucose diluted to 1000 c.cm. volume, with lemon added, was then drunk, and the bladder subsequently emptied every half hour. Amount and specific gravity were noted in each specimen of urine, and tests for sugar made; when the latter were positive, the percentage of sugar was observed by the polarimetric method and the total sugar excretion calculated. (Table II.)

TABLE II.

Time of observation in relation to glucose meal.. ..		Before.	Hours after.				
			$\frac{1}{2}$	1	1½	2	4
Volume of urine in c.cm....	T.I.B.	?	25	850	430	about 100	—
	H.V.A.	90	125	100	48	16	—
	M.	50	25	15	18	18	170
Total sugar excreted in grammes..	T.I.B.	Nil	Nil	Nil	Nil	Nil	—
	H.V.A.	..	tr.	..	..	..	—
	M.	..	0·1	0·06	..	..	Nil
Specific gravity of urine.. ..	T.I.B.	?	1020	1001	1001	1008	—
	H.V.A.	1022	1008	1004	1016	1020	—
	M.	1022	1018	1024	1026	1024	1012

From these results it appears that in two cases there was an immediate diuresis with passage of very dilute urine, but the third case showed no renal effect save a slight glycosuria.

(b) *Effects on the Blood-sugar.*—To determine these, samples of blood were taken from the median basilic vein of each subject at regular intervals, the moment selected being immediately before or after the voiding of urine. About 10 c.cm. of blood were collected on each occasion, it being desirable to do a more complete analysis. Blood-sugar was estimated by the Folin-Wu method. (Table III.)

TABLE III.

Time of observation in relation to glucose meal.. ..		Before.	Hours after.				
			$\frac{1}{2}$	1	1½	2	4
Blood-sugar in mg. per 100 c.cm....	T.I.B.	88	114	100	88	78	—
	H.V.A.	90·9	116	81	85	85	—
	M.	83	125	98	95	100	90

From these figures it is clear (1) that nothing approaching what is usually considered a hyperglycaemia was produced in any of our subjects; (2) that, in the subject M., who showed definite glycosuria, the rise in blood-sugar was proportionally greater than in the others; (3) that in all subjects

the maximum concentration of blood-sugar occurred in the first half hour after the ingestion of the glucose, and that after the first hour the glycosuria was not notably higher than when the subjects were fasting.

(c) *Effects on the Respiratory Exchange.*—With a view to examining these, samples of expired air were collected from one subject (H. V. A.) in a Douglas bag. The first sample was taken fasting, the second at a period one and half hours after the ingestion of 500 g. glucose. In both instances the subject was lying at complete rest on a couch, this rest having been begun 40 minutes before the first observation. (Table IV.)

TABLE IV.

Time of observation	Immediately before glucose.	1½ hours after glucose.
Corrected oxygen intake (c.cm. per minute)	240	244
Corrected CO ₂ output	192	199
Respiratory quotient	0·8	0·81

Any difference between the results of these two observations lies well within the limits of experimental error.

(d) *An Unexpected Effect Observed.*—A very striking hypnotic effect was observed in two of these subjects (T. I. B. and H. V. A.). In both cases the effect was so entirely unexpected by the subject, and was so strong, that there can be no question of suggestion alone being the cause of it. Some hours after the glucose, two and a half hours in one case and three and a half hours in the other, the subject experienced a feeling of sleepiness so profound that he was quite unable to carry on his habitual duties. It should be noted that, after the first half hour, no subject has remarked disagreeable effects; up to this time there was, in each case, a feeling of abdominal distension consistent with the rapid ingestion of so large a volume as a litre of fluid. In later stages the subjects chatted, read, smoked, and helped the observers with details. Each ate a small lunch, experiencing some appetite but no hunger, and in the cases named, in one before and in both immediately after, there was a somnolence so profound that he was impelled to lie down and was immediately overcome by a sleep described as being far deeper than any he had usually experienced. This sleep lasted for several hours in each case, and its depth may be gauged by the fact that the sleeper was on each occasion not roused by noises close to him so loud as to attract other persons from neighbouring rooms. Beyond this somnolence no subject experienced any untoward effect; gastro-intestinal symptoms were absent.

(e) *Problem of the Fate of the Ingested Glucose.*—G. Graham estimates the total amount of circulating glucose in the blood at less than 5 g. Is a large amount, such as was taken in these experiments, held up for a long period in the alimentary canal before absorption? We have conducted a few experiments with stomach tubage to explore this possibility. A tube was swallowed by one subject every quarter of an hour after taking 500 g. At the end of two and a half hours there was abundant glucose solution left in the stomach, but its actual amount was not determined as we were anxious not to disturb the experiment as a whole. For reasons given in earlier paragraphs of this paper, it is impossible to determine accurately the exact glucose-content of this solution, but observations on its reducing power, as tested by the quantitative Benedict test, give a fairly accurate index of its concentration in various samples. Tested in this manner the concentration of successive samples removed by tubage in the above experiment were found to fall from an original reading of 14 per cent. to a figure of 9·5 per cent. at the end of two and a half hours.

In two previous experiments the same subject had taken different quantities of glucose and subsequent specimens were examined for sugar, with the results shown in Table V.

TABLE V.

Time after ingestion in hours	1½	½	¾	1	1½	Strength of glucose.
Glucose percentage in gastric sample	(a) 16.6	11.2	11.3	5.3		200 g. in 400 c.cm.
	(b) 7.3	8.4	7.0	6.5	3.6	100 g. in 400 c.cm.

In these experiments the subject had had a light breakfast one and a half hours before taking glucose. The results, though clearly only roughly accurate, may be taken with that above as indicating that strong glucose solutions tend to be delayed in the stomach until diluted considerably. As regards the total time elapsing before absorption from the intestine is complete we are unable to offer an opinion. A second question suggested by these experiments is whether hyperglycæmia is avoided during the absorption of these large quantities of sugar by means of some mechanism which withdraws water from the tissues into the general circulation. With a view to determining this we have made fuller observations, by means of the Folin-Wu method, on the samples of blood withdrawn. The results are given in Table VI.

TABLE VI.

Time of observation in relation to glucose meal		Before.	Hours after.				
			½	1	1½	2	4
Urea* ..	H.V.A. M.	40.2 27.0	29.2 23.9	30.3 25.4	26.8 27.1	27.9 21.4	22.1
Non-protein nitrogen* ..	H.V.A. M.	34.2 37.6	30.2 34.6	28.6 33.3	31.6 30.7	33.3 25.6	33.3
Creatinin* ..	H.V.A. M.	? 1.7	1.15 1.7	1.1 1.7	1.25 1.6	1.4 1.4	1.4

* mg. per 100 c.cm.

Study of these figures shows a lowering of the concentration of the nitrogenous constituents of the blood; this supports the hypothesis that the absorption of sugar was in these cases accompanied by an hydræmia, fluid being withdrawn from the tissues into the main circulation. But any such hypothesis must be accepted with reserve until further evidence of dilution is obtained. Of the cases in whom this was observed, one had exhibited an early diuresis and somnolence at a later period. It seems curious that the kidney should deprive the blood of a relatively large volume of almost pure water at a moment when such diluting fluid is about to be in great demand. The somnolence is in accord with the hypothesis that active absorption will be accompanied by a relative hyperæmia in the splanchnic area and a consequent relative anæmia in the cerebral region; on the other hand, both subjects felt that the intensity of the drowsiness was much more akin to the effect of drugs of the chloral series than to mere post-prandial torpor. It remains possible that an important quantity of commercial glucose either escapes in the fæces or is destroyed by bacterial fermentation. We have no evidence on this point, but the entire absence of abdominal symptoms is strongly against it.

(f) *Effect upon Gastric Secretion.*—Our observations on this point have been limited to four cases. In these, stomach contents, removed at intervals after glucose ingestion, showed very little, if any, free hydrochloric acid to be present.

In two cases, where the fasting gastric content had been removed before taking glucose, there was no hydrochloric acid present at one, two, and two and

a half hours after the meal. In cases where the fasting juice has not been removed, the free acid was absent in one case and present in a concentration of 8 c.cm. N/10 only in the other. These results agree with those of Pavlov and others as to the minimal effects of sugars and dextrins in exciting gastric secretion.

CLINICAL OBSERVATIONS.

In a previous communication* one of us (T. I. B.) has referred to the value of glucose when administered in large quantities in certain diseases. It has been freely used for a number of years and in many countries, but it is, we believe, rare for it to be employed in really important amounts, and the solutions usually ordered are so weak that it is doubtful whether the effects obtained differ materially from what might be expected if water alone had been used. As an example, it is common practice to give weak glucose solutions per rectum, or subcutaneously, after severe operations, as it has been found that stronger solutions tend to produce irritation of the mucous membrane of the colon, or sloughing of the subcutaneous tissues. It is therefore a difficult matter to administer more than a small quantity of glucose in this manner. When given by mouth such difficulties do not occur, and though in the post-operative type of case oral administration is often impossible, in other cases we believe that the use of large quantities of glucose is frequently of great value.

For a long time and in a very large number of patients we have now made use of this preparation, giving quantities equal to one pound or more daily, and we believe that the following properties are those which give indications for its employment: (1) It is palatable and can be assimilated in quantities which materially increase the daily calorie-intake without greatly affecting the patient's appetite; (2) it is absorbed with less call for work by the digestive glands than almost any other substance; (3) physiological and clinical observations made by us show that it evokes very little, if any, secretion of hydrochloric acid by the stomach; (4) being in complete solution it evokes very little motor response from the stomach during its passage into the intestine; and (5) it provides the tissues with the ideal substance (glucose) for counteracting any tendency to acidosis.

Illustrative Clinical Cases.

The facts to be learnt from study of the details of clinical cases in which we have applied these indications are general rather than particular. For this reason it has been felt wiser to suppress such details in the present communication, giving merely the broader aspects of typical cases in certain groups.

GROUP A.—*Acute Infections.*—(1) Typhoid fever and lobar pneumonia: In three such cases in adolescents ½ lb. of glucose was added to the daily ration of food. No increase in intestinal gas formation was noted; no glycosuria resulted. (2) Pulmonary tuberculosis: In four cases 1 lb. of glucose was given daily in addition to usual diet. Glycosuria of less than 1 g. daily was observed occasionally in one case. No gastro-intestinal symptoms; progress uninterrupted. General appetite not affected by the addition to the diet. (3) Acute hepatitis during puerperium: A case of difficult labour with prolonged anaesthesia and some laceration of vulval tissues. Profound jaundice, pyrexia, vomiting, complete absence of bile from stools. Glucose in quantities exceeding 1 lb. daily, started immediately after the vomiting had begun to be controlled. Rapid and uninterrupted recovery. No glycosuria.

GROUP B.—*Six Cases whose Major Symptom was Hematemesis.*—All these were cases which had exhibited hamatemesis in such degree as seriously to endanger the patient's life. In two the primary disease was cirrhosis of the liver, in two gastric ulcer, in one carcinoma of the stomach, and in one the cause is unknown. All were treated by absolute rest, morphia and hyoscine hypodermically, and rectal feeding for some days. After half-hourly sips of

water had been tolerated without symptoms for 24 hours, glucose solution was added and within three days increased until 1 lb. daily was being taken; milk and carbohydrate gruels were added about a week later with simultaneous complete alkalisation on familiar lines. In the subsequent treatment the administration of glucose was continued and utilised as the main calorie-supply in the diet for a long period.

GROUP C.—Cases whose Major Symptom was Under-nutrition.—Many cases might be quoted under this heading, usually females of the type described by Robert Hutchison in his recent address on the "Chronic Abdomen."⁵ Often admitted with a diagnosis of "dyspepsia" or "visceroptosis," more exact diagnosis was impossible in the majority of cases. Several, although devoid of definite signs of activity, gave evidence of partly-arrested tuberculous disease. Glucose has been added to the diet in a manner similar to that indicated in Group A. The following representative case may be quoted:—

Female, aged 26, for two years had been the victim of a severe anxiety neurosis, owing to somewhat delicate physique impairing her capacity for physical work and having simultaneously the knowledge that that work was the main financial support of her mother and sisters. Headache, indefinite pains in abdomen and limbs, extremities cold and somewhat cyanosed, complete absence of appetite for food. Weight on admission 5 st. 1 lb. No signs of organic disease discovered. The blood-sugar, at different times of day, at this period was always in the neighbourhood of 70 mg. per cent., a figure lower than we have observed in any other subject apart from patients receiving insulin. The patient was kept in bed, told that rapid improvement would occur, and given no treatment beyond 1 lb. of glucose daily, instructions being given that all meals, apart from this, were to be very small, but that the patient was to finish them completely. After ten days, there had been an increase in weight of 3 lb., blood-sugar had risen to 110 mg. per cent., the extremities were warm and less cyanosed. In the third week, 5 units of insulin were given morning and evening, in addition to previous treatment. Continuing on these lines, the patient's condition improved steadily, the weight increasing by 2 lb. weekly, until she was discharged weighing 7½ stone and went to a convalescent home. It is worthy of note that on three occasions she had slight hypoglycæmic reactions in spite of the glucose administration.

Discussion.

These clinical observations are not set down with any claim to establishing a novel therapeutic action of glucose. We have detailed them rather in illustration of what we believe to be the simple and rational method of securing a diet which is of high calorie-value, very easily assimilable, and without disadvantage in non-diabetic patients. The problem as to whether advantage is to be gained by the simultaneous administration of insulin in such cases is not at present answerable. The observations on the concentration of sugar in the blood before and after the assimilation of large quantities of glucose in normal persons, which we have detailed in the early sections of this paper, show that hyperglycæmia is not produced. The fate of the ingested sugar remains obscure; is it immediately converted into glycogen in the liver and muscles? If so, is there any limit to the capacity of the body for such conversion, and is the glycogen converted into fat? Again, does the hypodermic injection of insulin aid such conversion in the absence of hyperglycæmia? All these are to-day unanswerable questions.

Our observations throw some light on the problem of the limit of carbohydrate tolerance in general. It has been rather generally imagined that such tolerance is strictly limited by some metabolic capacity of the body. Thus it is common to describe as one of the chief characteristics of pituitary insufficiency "a rise in carbohydrate tolerance"; examination of the literature makes it exceedingly difficult to understand what is meant by such description. Persons suffering from Fröhlich's syndrome are not known to exhibit hypoglycæmia, nor has their curve of blood-sugar following glucose administration been proved to differ from that of a

normal subject. The present work demonstrates that the only limit to the normal man's capacity for ingesting glucose is that imposed by his appetite. Glycosuria is only produced in a small proportion of such normal subjects and then in an unimportant degree. What, then, is an "increased carbohydrate tolerance"? The only possible explanation we have met with is that of H. Cushing,⁶ who, speaking of persons with Fröhlich's syndrome, says that they are proverbially sweet-tooths.

Summary.

1. "Glucose B.P." is a substance which allows large quantities of glucose to be administered in palatable form and at a low cost.
2. Its exact chemical composition is difficult to determine, but it is shown to contain arsenic in negligible traces only and to have a calorie-value of about 1000 large calories per pound.
3. Normal persons can assimilate quantities of 200–500 g. in one dose without passing more than a trace of sugar in the urine.
4. The main effects on subjects who took 500 g. in this manner were (a) diuresis, (b) a rise in blood-sugar not greater than what occurs after a normal meal, (c) no change in the respiratory quotient, and (d) a marked hypnotic effect in two cases.
5. Large quantities of sugar taken in this manner appear to be detained and diluted in the stomach.
6. There is evidence of a dilution of the blood during such experiments.
7. Large quantities of glucose have been added to the diet as a therapeutic measure in many clinical cases, particularly in (a) acute infections; and (b) cases with marked undernutrition. Distinct benefit appears to have resulted and no ill-effects have been observed. In some of these cases the glucose administration was accompanied by small doses of insulin.

This work forms part of a report to the Medical Research Council. Part of the expenses were defrayed by grants from the Royal Society, through the Government's Grant Committee. We wish to express our obligation to Mr. W. Lawson for analyses of samples of commercial glucose and to those students of the Middlesex Hospital who have aided us by acting as subjects for experiment.

DISLOCATION OF THE SEMILUNAR BONE.

WITH NOTES OF A CASE.

By CHARLES NOON, F.R.C.S. ENG.,

ASSISTANT SURGEON, NORFOLK AND NORWICH HOSPITAL.

DISLOCATION of the semilunar bone of the wrist is an unusual injury. Before the use of X rays the condition was rarely recognised. A fair number of these cases have been reported since, but it still frequently happens that the nature of the injury is not recognised when the patient first comes under observation, the condition being thought to be due to a sprain of the wrist—a diagnosis which far too often satisfies both doctor and patient. It not infrequently happens that the so-called "sprained wrist" is proved on further investigation to be a definite bony injury to the wrist-joint which can sometimes be diagnosed by careful clinical examination, and at other times requires the use of the X rays before a

diagnosis can be made. Dislocation of the semilunar bone may occur alone or it may be associated with a fracture of the scaphoid. Both these conditions, which have to be diagnosed from a Colles's fracture, give rise to very definite symptoms and physical signs which, if careful observations are made of the injured parts, should not be overlooked. A definite diagnosis can often be made clinically, and confirmed by the use of the X rays.

Diagnosis.

The physical signs of a dislocation of the semilunar bone are deformity of the wrist-joint, which, when viewed laterally, suggests the silver-fork deformity of a Colles's fracture, but on careful examination the styloid processes of the radius and ulna are found to bear their normal relations one with another. A tumour is felt and seen on the flexor surface of the wrist-joint, pressure on which causes pain in the distribution of the median nerve, the tumour feeling like a displaced carpal bone. There is practically no movement in the fingers or thumb, the incapacity from which is usually far greater than that seen in cases of injury of the scaphoid and in Colles's fracture. When both wrists are looked at from the palmar surface the deformity, as compared with that of a Colles's fracture, is striking and characteristic in its difference. The hand of the injured extremity appears to be that of a different person; it is smaller and shorter, and if the injury is of long standing there is almost sure to be much wasting of the muscles of the forearm and may be some wasting of the muscles in the hand supplied by the median nerve. The condition has also to be distinguished from a simple fracture of the scaphoid bone, the symptoms and physical signs of which are said often to be very definite—namely, (1) a localised swelling in relation to the radial half of the flexor surface of the wrist-joint, (2) acute tenderness in the anatomical snuff-box when the hand is adducted, (3) limitation of extension of the wrist by muscular spasm, any attempt to overcome which by force causes unbearable pain.

Treatment.

The treatment of dislocation of the semilunar bone depends on the stage at which the injury is recognised and seen, and on the presence or absence of the common associated injury—namely, fracture of the scaphoid. In general, the treatment can be considered under the following headings:—

(1) *Rest and massage without attempted reduction of the dislocated bone.* This is the line of treatment which has been adopted in cases in which the diagnosis has in the first place been missed. It is not likely to be followed by satisfactory results. When such cases come under observation it is found that there are much permanent stiffness of the wrist, weakness of the grip, and pain in the distribution of the median nerve. The possibility of improving such conditions when seen after a considerable lapse of time is not good.

(2) *Early or late reduction by manipulation of the dislocated bone followed by rest, massage, and movements.* Immediate reduction of the dislocated bone is the ideal treatment and will be followed by the best results. The best method of reducing the dislocated bone has been described by Codman and Chase. After carrying out careful researches on the movements of the wrist-joint and on the mechanics of dislocation of the semilunar bone, they say: "Since dislocation forward of the semilunar bone takes place by hyperextension, its reduction must take place by hyperflexion. Hyperextension is first made, to drag the convex surface of the semilunar back into contact with the radial articular surface and then, while the semilunar is prevented from rolling forward by pressure of the two thumbs of the surgeon at the anterior lip of the radius, hyperflexion is made over the surgeon's thumbs by an assistant. This allows the articular surface of the os magnum to again roll over the posterior horn of the semilunar bone to its proper facet."

From a study of recorded cases it seems that reduction by manipulation may be successful even after as long a time as a month after the injury. It is always advisable, therefore, to try to reduce the bone if there is any reasonable hope of this method of treatment being successful.

(3) *Reduction by an open operation* or excision when reduction cannot be successfully performed. If reduction fails an open operation will be indicated, by which it may be possible to reduce the bone, but if this cannot be done the bone should be excised.

(4) *Late Excision of the Bone.*—In long-standing cases in which there have been secondary changes in the bones of the joint, it is unlikely that reduction will be possible even by an open operation. The indication for excision in this type of case is pain in the distribution of the median nerve. If the dislocated bone presses on the nerve excision will relieve this pain, but the condition of the joint will not be much improved in these old cases. The recorded case was a simple dislocation of the semilunar bone of the right wrist, seen five days after the injury. All the typical signs and symptoms were present. Reduction was attempted both by manipulation and by open incision, but it was not found possible, even after so short a time as seven days. The bone was therefore removed. The wrist was "put up" in an extended position for a few days, massage and movements were started as soon as possible, with the result that the patient made a rapid recovery and was only left with a very slight disability.

Record of Case.

Injury to the Right Wrist-joint; Dislocation of the Semilunar Bone; Operation, Excision of the Dislocated Bone. Result: Recovery with a useful wrist.

E. R. H., a man aged 28, was sent to me by Dr. A. R. Kay, of Blakeney, on Feb. 28th, 1924, complaining of an injury to the right wrist-joint received while starting a motor-car on Feb. 24th. Since the injury the patient complains that he has not been able to use the wrist and fingers of the right hand owing to the pain and swelling.

Condition on Admission.—The right wrist is swollen, there is a prominence on the flexor aspect of the joint, the dorsal aspect of the joint is also swollen and prominent. On comparing the palmar surfaces of both wrists and hands the injured hand looks shorter and smaller than its fellow. The wrist and fingers are held slightly flexed and the patient is unable actively to extend the wrist or fingers, while passive movement of wrist and fingers is only possible to a very slight extent and then only with severe pain. The styloid processes of the radius and ulna bear their normal relations with each other. There is a hard, bony, irregular fixed swelling on the flexor aspect of the wrist-joint which feels like a dislocated carpal bone. No crepitus is felt. There is some numbness of sensation over the distribution of the median nerve, ulnar sensation being normal.

X Ray Examination.—There is a forward dislocation of the semilunar bone. There is no other evidence of injury to the bones of the carpus or wrist-joint.

Operation.—The patient was anaesthetised on March 3rd. It was not found possible to reduce the dislocation by manipulation. A vertical incision was therefore made over the flexor aspect of the wrist-joint, the incision being half an inch to the ulnar side of the tendon of the flexor carpi radialis. The deep fascia was incised, and the median nerve was found tightly stretched over the superficial aspect of the dislocated semilunar bone. It was carefully retracted and the semilunar bone exposed. Reduction was not even then possible by an open operation. The bone was therefore excised and the wound closed without drainage.

Progress.—The wrist was put up in an extended position for a few days and massage and movements started as soon as possible. The wound healed by primary union. The patient regained full movement in the thumb and fingers, and eight weeks after the operation the movements of the wrist were only very slightly limited, about one-eighth of full movement being lost, but the grip was strong and the disability, even so soon after the operation, was slight. There was no pain.

Clinical and Laboratory Notes.

A CASE OF MENINGITIS FOLLOWING LUMBAR PUNCTURE:

IRRIGATION; RECOVERY.

By C. P. SYMONDS, M.D. OXF., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN FOR NERVOUS DISEASES, GUY'S HOSPITAL.

MENINGITIS as a sequel of lumbar puncture is a rare occurrence, and it is therefore of interest and importance to record a case in which treatment by irrigation was followed by recovery.

The patient, a male aged 42, was admitted to hospital in July, 1924, for pain in the back and legs following a lumbar puncture which had been performed for purposes of diagnosis three days previously.

History.—The history was that some 15 years previously he had first noticed some weakness of the left leg. This gradually increased and spread to the left arm, where it became associated with tremor. The right limbs were subsequently involved, and the condition finally was symmetrical. He gave a history of venereal infection (gonorrhoea) in 1898—before the onset of the nervous symptoms—and of several attacks of malaria.

In view of the early age of onset and the history of venereal infection the suspicion was entertained that this was possibly a case of mesencephalitis syphilitica, and it was for this reason that lumbar puncture had been performed.

probably a local collection of intrathecal pus. As the man's condition appeared to be desperate, I conceived the idea of attempting to wash this out by forcible irrigation. Leaving the lumbar needle in situ, I therefore performed a cistern puncture. The fluid obtained was under pressure and slightly turbid. Leaving the cistern needle in place, I then fixed a large barrelled syringe to the lumbar needle and attempted to inject a quantity of normal saline. This at first met with obstruction. When the pressure was finally increased almost to the maximum to be obtained the patient cried out with pain, and the fluid began slowly to flow out of the syringe. At the same time a blood-stained and turbid fluid began to flow from the cistern needle. In this way 50 c.cm. of normal saline were forced from below upwards through the subarachnoid space. Towards the end of the procedure the escaping fluid, though still blood-stained, was less turbid. Subsequent investigations showed in the pus from lumbar puncture abundant staphylococci, with a pure growth of *Staph. aureus* on culture.

The chemical report upon the first specimen of cistern fluid (before irrigation) was: Protein, 0.11 per cent.; chlorides, 0.702 per cent.; about 70 cells per c.mm.—about one-third of which appear to be polymorphs. After the irrigation the temperature gradually fell and was normal on the morning of the 17th. At the same time the patient's general condition improved, and he became more rational.

Lumbar puncture was performed again on the 16th, and a drop or two of pus obtained by aspiration. The temperature rose to 101° on the evening of the 17th, but was never subsequently above 100°, while the improvement in the general condition was maintained. Signs of meningeal irritation being still present lumbar puncture and cistern puncture were both performed on the 19th. The cistern fluid was clear but contained 0.09 per cent. protein and white cells in excess. From lumbar puncture a trace of pus was obtained

Temperature Chart of a Case of Meningitis following Lumbar Puncture.

It was ascertained that the usual technique had been employed, the skin having been prepared by washing with ether and painting with picric acid. The only questionable factor was the sharpness of the lumbar puncture needle which had been used on a previous occasion.

The patient experienced no ill-effects until 48 hours after the puncture. He then felt some pain about the left iliac crest, which later increased in severity and extended to the bottom of the spine and buttocks. On the following day he had shooting pains in his legs and experienced difficulty in standing.

Condition on Admission.—When seen on admission (July 11th) he presented the typical appearance of a case of paralysis agitans, with mask-like face, characteristic rigidity, and "pill-rolling" tremors of the hands. He complained of severe pains in the regions described. The temperature (mouth) was 100° F. Kernig's sign was positive. The tendon-jerks were present and equal on the two sides. The abdominal reflexes were present and equal. No plantar responses were obtained. No abnormality of sensation was detected. There was no evidence of sepsis at or around the site of lumbar puncture.

July 12th: Temp. 100°. Patient complaining of intense pain; retention of urine; tendon-jerks present and equal. Lumbar puncture thrice attempted but no fluid obtained. 14th: Temp. 103°. Incontinence of faeces in addition to retention of urine; knee- and ankle-jerks absent. Patient delirious. 15th: Temp. 105.4°. Patient in a low muttering delirium. I saw him this day and thought him moribund. On performing lumbar puncture I obtained no fluid, but on attaching a syringe to the needle aspirated a small quantity of thick purulent material. I concluded that there was

by aspiration. A final lumbar puncture was performed on the 21st when a trace of pus was again obtained on aspiration.

Since July 15th the lower limbs had appeared to be completely paralysed. On the 23rd power began to return, on the 24th the right knee-jerk was obtained, the others being absent, as also was the left lower abdominal. The patient could lift his right heel clear of the bed, and had some movement in his toes. He complained of numbness in the legs, but no definite sensory loss was made out. He continued to improve and left hospital on August 8th at his own request. His evening temperature had then not been above 99° for four days, and his general condition was good. He still, however, had retention of urine and imperfect control over the anal sphincter. The lower limbs were weak but he was able to sit up. The tendon-jerks were absent except the right knee-jerk. He was unfortunately not seen again, but wrote three months later to say that he had recovered sufficiently to walk and was going on a sea voyage.

Commentary.

In commenting upon this case one must admit the risk, albeit extremely small, of septic meningitis as a result of lumbar puncture, even when performed under aseptic conditions by an experienced worker as in the present case. It is the same risk of sepsis which is encountered in every surgical operation. It must have been the unfortunate experience of most surgeons to have known sepsis occur in such operations, for instance, as those for hernia and varicocele. The reason would seem to be that it is impossible to

sterilise absolutely the deeper layers of the skin. In such an operation as lumbar puncture it is almost inevitable that micro-organisms from the skin will occasionally be carried into the thecal space upon the point of the needle. This risk must be considerably increased when the point is in the least blunt or irregular, or the stilette not bevelled flush with the needle. In the opinion of the writer, therefore, a needle should always be subject to careful inspection after use, and if defective in any of these ways should be sharpened before being used again.

The measure of irrigating the subarachnoid space was undertaken as a desperate remedy when the patient appeared to be in extremis. Short of open operation, forcible washing through provided the only measure of evacuating the intrathecal abscess. The risk of setting up a further extension of the meningitis was seriously considered before the procedure was adopted, but when the fluid from the cistern puncture appeared turbid the conclusion arrived at was that the whole extent of the subarachnoid space was already infected—whether, indeed, staphylococci were present in the cistern fluid is a point which was unfortunately not settled. Irrigation from above downwards was entertained, but at once dismissed as dangerous. It was realised that the fluid would have to be introduced under a pressure which, if directed towards the medulla, would have almost certainly resulted in an immediate fatality.

Whether the patient would have improved with repeated lumbar punctures without irrigation is a matter open to doubt. A review of the clinical history and temperature chart suggests that the irrigation was the deciding factor in promoting recovery, and the case is recorded in the hope that it may be of use to others who may chance to encounter such a rare and disastrous complication of lumbar puncture.

My acknowledgments are due to Dr. A. P. Beddard for permission to publish the notes of this case.

A CASE OF ACQUIRED ACHOLURIC JAUNDICE.

BY C. E. K. HERAPATH, M.C., M.D. LOND.,
ASSISTANT PHYSICIAN, BRISTOL ROYAL INFIRMARY;
AND

A. D. FRASER, M.B., CH.B. GLASG.,
PATHOLOGIST TO THE INFIRMARY.

ACHOLURIC jaundice of the acquired type is a rare disease and comparatively few cases have been treated by splenectomy; the following case may therefore be of interest.

The patient, a man aged 38, had been jaundiced for 11 years. The colour of the skin and eyes varied from time to time, and he complained of severe itching of the skin at intervals. He noticed that his stools were apparently normal in colour, whereas the urine was dark. On four occasions he had attacks of abdominal pain and vomiting accompanied by a great increase in the jaundice.

When examined he complained of weakness and shortness of breath on walking any distance. His skin was of a deep lemon colour. The spleen was greatly enlarged, the lower pole being 1 inch below the umbilicus. The liver extended 1½ inches below the costal margin. The blood Wassermann test was negative.

The result of the blood examination was: total reds, 2,000,000; total whites, 6400; reticulated reds, 14 per cent.; hæmoglobin, 45 per cent. Differential count: polymorphs, 57 per cent.; lymphocytes, 38.5 per cent.; large mononuclears, 3 per cent.; eosinophiles, 1 per cent.; myelocytes, 0.5 per cent. The red cells showed marked polychromatophilia and punctate basophilia. There was no poikilocytosis, but anisocytosis was marked, and was due to the presence of many microcytes. In a count of 200 leucocytes 10 normoblasts were noted. The fragility of the red cells was increased, hæmolysis beginning in 0.58 per cent. and being completed in 0.34 per cent. saline. The test for auto-agglutinins in the blood-serum was positive. The result of the van den Bergh test was: direct reaction negative, indirect reaction positive (15 units of bilirubin). The urine was pink in colour and contained much urobilin. The test for bilirubin was negative. The stools appeared normal, but were very dark brown in colour, and gave an intense positive reaction for bile pigments. The levulose test for hepatic insufficiency was,

positive, the result being: statim, 0.129 per cent.; ¼ hour after, 0.148 per cent.; ½ hour after, 0.157 per cent.; ¾ hour after, 0.166 per cent.; 1 hour after, 0.156 per cent.; 1½ hours after, 0.133 per cent.

The above findings—viz., non-obstructive jaundice and severe anaemia, with an increased number of reticulated red cells, together with increased fragility of the red cells—confirmed the clinical diagnosis of acholuric jaundice. The presence of auto-agglutinins in the blood-serum pointed to the fact that it was of the acquired type.

The spleen was removed by Mr. C. F. Walters on Sept. 22nd. The removal was effected without much difficulty, there being few adhesions. The liver was found to be enlarged but smooth, and no gall-stones could be detected. The spleen weighed 1200 g. and measured 23.5 by 15 by 7.5 cm. The capsule was fairly smooth, but showed two adhesions, one near the hilum and the other on the anterior surface. On section the pulp was dark red in colour, slightly soft, but not friable. Malpighian bodies could be distinctly seen but appeared smaller and more widely separated than in a normal adult spleen.

Microscopic examination showed that the venous sinuses and the lacunar blood spaces in the splenic pulp were overfilled with blood, with the result that the cells of the pulp cords were widely separated from one another. The Malpighian bodies were far apart and appeared somewhat smaller than normal. This would seem to have been the effect of general congestion and not to atrophy or necrosis, as they were normal in appearance and many showed germ centres. There was an increase in the amount of pigment present, which was found mostly in the large phagocytes lining the sinuses. There was no evidence of fibrotic changes in the capsule or connective-tissue framework, nor could any change be seen in the walls of the blood-vessels. These findings suggested that the increase in the size of the spleen was the response of the organ to a demand for increased activity, and not due to the direct action of any toxic agent.

The recovery after operation was uneventful, except that he had a temperature of 101° F. and complained of abdominal pain on the eighth day. However, enemas completely relieved him. The results of a blood examination on this day were: total reds, 3,900,000; total whites, 29,580; reticulated reds, 0.4 per cent.; hæmoglobin, 60 per cent. Differential count: polymorphs, 91 per cent.; lymphocytes, 3.5 per cent.; large mononuclears, 4.5 per cent.; basophiles, 1 per cent. The red cells showed slight inequality in size. There was no polychromatophilia or punctate basophilia, and no nucleated reds were seen. The fragility of the red cells was the same as before operation and the auto-agglutination test was still positive. The van den Bergh indirect reaction showed 2.5 units of bilirubin. Urobilinuria was still present but was not marked. On the ninth day the patient was clinically free from jaundice. The van den Bergh indirect reaction showed 1.25 units of bilirubin and the urine a trace of urobilin. On the tenth day the van den Bergh indirect reaction showed 0.5 units of bilirubin, and urobilinuria was absent. On the thirteenth day the levulose test for hepatic insufficiency was found to be negative. The same result was obtained two weeks later.

Twenty-nine days after operation the patient had put on 13 lb. weight. The blood examination on this day was: total reds, 4,960,000; total whites, 8750; hæmoglobin, 90 per cent. Differential count: polymorphs, 46 per cent.; lymphocytes, 51 per cent.; large mononuclears, 1 per cent.; eosinophiles, 2 per cent. There were no abnormal red cells, and the auto-agglutination test was negative. Two weeks later the red cells had reached 5,200,000 and the hæmoglobin was 90 per cent., the polymorphs being 51 per cent. and lymphocytes 39 per cent. The auto-agglutination test was again negative but the increased fragility of the red cells remained. On Dec. 29th the red count was 5,760,000 and the hæmoglobin 100 per cent. The fragility test was about the same as before operation, hæmolysis beginning in 0.58 per cent. and being complete in 0.32 per cent. saline.

Commentary.

There would appear to have been two factors at work in this case: (1) the increased fragility of the red blood cells, and (2) the presence of auto-agglutinins in the blood-serum. The former remained after removal of the spleen which is in accordance with the findings of others; the latter, the auto-agglutinins, disappeared after splenectomy, which suggests that these abnormal substances may have been produced in the spleen. The complete disappearance of symptoms after splenectomy has been found in both congenital and acquired cases, but in this case it has been shown that the hepatic efficiency has been restored by the operation. It is possible that the overwork of the liver in the excessive excretion of bilirubin has damaged the efficiency of the liver cells, and that the return to normal is due to the rest after the excessive hæmolysis has been stopped.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

A MEETING of this Section was held on Feb. 13th, Sir ARNOLD LAWSON, the President of the Section, being in the chair.

The late Sir Anderson Critchett.

The PRESIDENT made sympathetic reference to the recent death of Sir Anderson Critchett, and paid a high tribute to him as a distinguished ophthalmologist, as a colleague, and as an English gentleman, declaring that in those privileged to enjoy his intimate friendship he inspired a feeling stronger than mere high regard. Mr. Ernest Clarke, as a friend of 40 years, seconded the vote of condolence with Lady Critchett and the members of the family, and it was carried in silence by members rising in their places.

Etiology of Miners' Nystagmus.

Dr. T. L. LLEWELLYN, in a general review of this subject, exemplified by charts, graphs, tables, and photographs, said he regarded miners' nystagmus as an occupational disease of the general nervous system, one of gradual onset, and chiefly affecting workers at the coal-face. However, 25 per cent. of all men employed underground showed, on being examined, signs of the disease. The incidence of certified cases had shown a sharp rise since the inclusion of miners' nystagmus in the Schedule of Industrial Diseases, and particularly since the broadening of the definition in 1913, and the difficult economic conditions of the post-war period. He contended that the chief factor in the production of the disease was the *deficient illumination* of the coal-mine on account of the low candle-power of the lamps used and the absorption of light by the coal. The collier was, he said, a skilled workman, but he was required to do accurate work in a poor light. It appeared that the more the collier had to use his pick the more likely was he to develop the disease. Delay in dark adaptation and an increased retinal susceptibility were frequent symptoms. The general influence of light was shown by the facts that the condition was more prevalent in winter, the symptoms came on after dark, and the recovery-rate was greatest in summer. There was proportionally more of the disease in urban than in rural districts, and more among men working some seams than among others. Depth of the workings and the thickness of seams were not such important factors as the age of the workman, the character of the shale, and the amount of attention which the worker paid to his disease.

The Personal Factor.

Dr. Llewellyn regarded the personal factor in the disease as a very important one, for men suffering from illness due to accident or other cause very frequently attributed their incapacity to the nystagmus which they had had while working for years. The development of a neurosis helped men to escape from their uncongenial surroundings. Most cases of miners' nystagmus did not appear to have any neurosis; in a second group the disease was well marked and there were neurotic symptoms, while in a third class the dominant condition was neurosis and the nystagmus was slight or indefinite. This neurosis had no special characteristics, and its treatment was the same as for other neuroses. The provision of suitable work helped the recovery-rate, and improved the rate of incidence. Idleness among subjects of the disease resulted in such deterioration as to render the patients unemployable.

Results of Working in Dim Lights.

Prof. J. S. HALDANE said it was now clearly established that miners' nystagmus was brought about by using the eyes for the guidance of muscular movement when the absolute differences in luminosity

of the objects seen were very low. Acuity of vision began to fall off seriously with low illuminations, and it might be sufficiently low to prevent white objects being distinguished from black ones, however large. Even with very moderate illumination, acuity of vision was much greater in the centre than at the periphery of the visual field. In foveal vision with sufficient luminosity the impression of consciousness of an object on which the eye was fixed was a lasting one; but with very low luminosity foveal vision lost its lasting character. A result of the impossibility of fixing the eye on the object was that the eye wandered about, picking the object up only momentarily with the fovea, then losing it again. The fatigue thus induced, the speaker considered, was the origin of the ultimate disturbance in ocular coördination which constituted miners' nystagmus. In mines where the men used oil cap-lamps there were no cases of nystagmus. The illumination required to prevent nystagmus was that which would permit lasting foveal vision, and so of fixation on the objects seen. Mr. Pooley had shown that the tendency to nystagmus was not dependent on defects of accommodation, but might depend largely on variations in the threshold for lasting foveal vision. In conclusion, Prof. Haldane said he did not consider that nystagmus was due in any way to the gases present in coal-mines.

The Quality of Illumination in Mines.

Mr. H. S. ELWORTHY (Ebbw Vale, Mon.) said that when investigating the cause of nystagmus he was much impressed by the blackness of the coal-mines, and he thought that illumination could best be increased by putting in light colours, which would reflect more light into the eyes of the miner. By better illumination he did not necessarily mean greater candle-power. If what he termed the "chromophotic index" was over 500 he believed there would be no nystagmus. When an oil lamp was taken into a mine, its candle-power was diminished as the yellow and orange rays disappeared, leaving a bluish-white light. On the lamp being again brought into the fresh air these yellow rays reappeared. Blue and violet rays were the most irritating to the eyes, and when objects of these colours were looked at for any considerable time they tended to disappear. It was recognised that the eyes needed to be protected from ultra-violet rays, otherwise damage to them might result. Exhaustion of the visual purple by those rays might well explain the eye movements in nystagmus, as the eyes avoided any continual fixing of these rays on any one part. Though the Ceag and Oldham lamps had a greater candle-power in a mine than an oil lamp, their light was of a worse quality than that of the oil lamps they replaced. Steam coal reflected twice as much blue as did house or anthracite coal, and among workers at the former nystagmus was much the more common. The carbon filament lamp produced an excellent light for the purpose and could be regarded as ideal. What was being aimed at was a filtering glass which would reduce the blue to 5 or 6 per cent. It was agreed that, from the point of view of the prevention of nystagmus, a light of 0.9 candle-power was required in order to be within the margin of safety. In the Ebbw Vale group of collieries, with 4600 men underground, there were 42 cases of nystagmus in 1914, while 10 years later there were only 7, and the only change which had been made in the equipment of the miners in the interval was the substitution of a yellow glass for the clear crystal. Mr. Elworthy said that when wages were high there were fewer cases of nystagmus—e.g., in 1917 there were only three instances among 5000 men. At the present time a man was financially better off by claiming the 35s. weekly compensation than by working three days a week. Given a correct glass and a sufficient light, he thought nystagmus would not occur at all.

The Compensation Factor.

Prof. E. L. COLLIS exhibited diagrams to show that the supposed recent increase in the incidence of miners'

nystagmus was not a real one. There had been an increase in the number of claims for compensation for the disease, which was, in his view, a combination of a physical symptom with underlying neurasthenia. Oscillation of the eyeballs was present without causing inconvenience in from 20 to 30 per cent. of miners working with poor illumination. In Belgium, payment of compensation on account of nystagmus was not continued longer than six months. In this country there was no time-limit, and the increase in the claims for compensation had been much greater since 1913, the year in which the Third Schedule included compensation for "a disease known as miners' nystagmus, whether the symptom of oscillation of the eyeballs be present or not." The weekly compensation figure had been increased from 20s. to 35s. He contended that the figures showed that when the economic life of the mining industry was unhealthy, the psychology of those employed in it became unhealthy too, and that then a certain number of latent cases from the potential reserves became manifest. It was the neurasthenic factor which was of urgent importance.

Mr. BINNS, representing a colliery owner's insurance company, said he believed many men were certified as having miners' nystagmus who had not that condition, the reason being that not all certifying surgeons were experts in regard to that disease. An appeal against such a diagnosis was made in 32 out of 428 claims, and in only 4 of the 32 was the appeal not sustained. Canary-coloured glasses for the miners had been found to be very useful, but it was not to be expected that they would produce an immediate cure. He expressed the hope that the profession would find a cure, so that a man suffering from nystagmus could be sent to hospital and return healthy. It was very difficult to find work on the surface for all the sufferers from miners' nystagmus.

Mr. G. H. POOLEY (Sheffield) spoke on the personal factor in the aetiology of this disease, dividing this factor into that in the observer and that in the person observed. The right attitude for the observer was to examine the whole of the men working in a particular mine, and as far as possible, under the actual conditions in which they did their work, and so ascertaining what percentage of the men showed nystagmus, and to what degree. He had recently been testing vision in an extremely dim light, working with as little as 0.00006 candle-power. The normal eye could still detect colour with this, the visual acuity being $1/72$ of the normal. A relative central scotoma was experienced, the object looked at rapidly becoming dim, though on the temporal side was a point at which the visual acuity was greater than at the point of fixation. There was, under these conditions, much flickering and fatigue, and a moving object was seen more readily than was a stationary one. It was very difficult to prevent the eyes oscillating when working in a very dim light. With regard to the personal factor in the worker, the miner could still work, despite his having a very marked degree of oscillation. Some played cricket in quite good teams, and some had both defective vision from cataract as well as nystagmus, but they refused to apply for compensation and continued to get coal. It was to the financial advantage of the men that they should be under the compensation clauses than under the National Insurance Act. Much of the so-called "hysteria" met with in this association was really *malade imaginaire*.

The Effect of Mine Gases.

Dr. F. ROBSON remarked that the number of certified cases of miners' nystagmus was getting very large, and said that the knowledge derived from the intensive work of coal chemists helped the clinician to visualise a possible chemical relationship of coal to the neurological defects of the miner. The class of coal in connexion with which nystagmus chiefly arose was the bituminous, which contained a high percentage of volatile matter. Subjects of nystagmus might recover, but their return to the pit was marked

by a recurrence. The disease was not found in workers in other kinds of mine, but it was significant that in one ironstone mine which had a single seam of coal running through it, cases of nystagmus occurred. Owing to its volatile constituents, bituminous coal was very liable to spontaneous combustion. There was no nystagmus in the coal-fields of America and South Africa, but there was a good deal of the disease in the coal-mines of New South Wales.

Dr. MILLAIS CULPIN contended that the symptoms associated with nystagmus were psycho-neurotic, and some of them were seen in the mental cases resulting from the war. Prominent among them were anxiety neuroses—economic anxiety in the case of the miner—photophobia, and head tremors. He sought to establish a close parallel between miners' nystagmus and the so-called shell-shock in soldiers.

Dr. C. F. HARFORD supported the view put forward by Dr. Culpin, contending that the morale of cases of miners' nystagmus was defective, and there was a readiness to avail themselves of the avenue of escape from their irksome conditions of employment.

Dr. H. W. EDDISON also argued along the same line, pointing out that an accident such as a blow on the leg, or domestic grief, determined the onset of nystagmus. Some showed an acute exacerbation during examination into their condition.

Mr. H. E. MITTEN, a civil engineer in a communication which was read, stressed the constrained attitude of the men in an insufficient light, but said there was a great difference among the men. He had 7000 men working underground under his own personal supervision, and there had been among them an improvement in the incidence of nystagmus from 0.95 per cent. in 1913 to 0.56 per cent. in 1924, and this he attributed to better illumination. He considered, from much observation, that the miner who found himself affected by nystagmus should endeavour to continue active exercise by working in some capacity, for idleness was likely to aggravate the disease.

Exhibition of Cases.

Mr. LINDSAY REA showed a patient who had presented the signs of orbital tumour, but was subjected to vigorous antisyphilitic treatment and recovered $6/6$ vision in each eye.

Optic Nerve Tumours.

Mr. HUMPHREY NEAME showed a patient, aged 45, with a tumour of the optic nerve. The left pupil was displaced outwards to the extent of 2 mm., but the eye movements were full in all directions. No nasal or sinus disease was discoverable. The age of the patient rendered endothelioma likely, and he gave other reasons for this.—Mr. WILLIAMSON NOBLE showed a case of somewhat similar nature.

Mr. KENDALL exhibited a patient with angioma of retina.

SECTION OF ODONTOLOGY.

Drugs Used in Local Anæsthetics.

A MEETING of this Section was held on Feb. 23rd, Mr. J. G. TURNER, the President, in the chair.

Mr. F. N. DOUBLEDAY gave a report upon some drugs and solutions used in local anæsthetics. He said that for some time past he had concluded that sufficient attention was not paid to the character of the solutions which were used in regard to the effect which they had in causing those minor discomforts, swelling and after-pain, which had been, in his experience, the only unsatisfactory results from the use of local anæsthetics in dental practice. He had, therefore, been working on this problem for about a year, and the description of all that had been done by him and his co-workers on the subject was too long for a single contribution.

He first endeavoured to get an idea of the graphic structure of the drugs, and Prof. Gibson, of Guy's Hospital, had drawn out a table showing the graphic structure of some of the drugs in question. This was thrown on to the screen, and showed how slight a change

took place in these local anæsthetic compounds. Efforts were made to ascertain some tests for novocaine. The most reliable tests for drugs used in local anæsthesia of which he was aware were those in the second volume of Martindale's Pharmacopœia, but they were not absolute for all, and the absence of absolute tests for some drugs was a serious drawback. It was hoped to test dialysed solutions of novocaine against other drugs and examine the filtrate, but the absence of tests for the drugs precluded that. He had been dealing, however, with some important problems connected with temperature and evaporation. A local anæsthetic solution was boiled in the same manner as for a patient, and it was then put into a previously boiled syringe and allowed to become quite cold. A thermometer was kept in a tumbler of boiling water, so that the initial temperature of the thermometer should not in itself cause any alteration of the fluid in the barrel of the syringe. Screwing on to it a dummy head, the upper part of the syringe was removed with the barrel, and the bulb of the thermometer was placed into the barrel of the syringe. The result was a solution which was within a degree of body temperature. It was found that if the containing mugs which were supplied for boiling were permitted to boil furiously for a minute, or even for half that time, they would be found to contain only 2.5 c.cm. instead of the original 3 c.cm. The result of this was that, instead of injecting into the patient a solution which was practically isotonic with the fluids of the body, it was one which was unduly concentrated, and the patient had after-pain, swelling, stiffness, and discomfort. The same was true of short test-tubes. The longer a test-tube, the better, for fluid which evaporated in the boiling would re-condense on the upper part of the tube and find its way back to the bottom of it. A further matter, which was far from negligible, was the reaction of the containing glass upon the fluids; this glass should be relatively free from soda, otherwise the soda would dissolve and so affect the alkalinity or degree of acidity of the solution.

Experiments on Frogs' Hearts.

Mr. Doubleday said that much of the experimental work which had been done on the action of local anæsthetic drugs consisted in their injection either into the blood-stream or into the heart. In the former case an effect was produced differing from that following injection into connective tissue. When a drug like novocaine was injected into the tissues of the body it must first come into contact with the cells, and the manner in which that could be brought about was very interesting. In control experiments on man, he and his colleagues had done many mandibular injections upon themselves and upon others. The novocaine did not act on the central nervous system, but it was placed in the nerve trunk. One must think that the drug did come into contact directly on the protoplasm of the axis-cylinder process and inhibited its activity. The mandibular sensations were definite under local anæsthesia; there was first a tingling sensation of the lip, and if after five to ten minutes one bit on one's teeth the periodontal sensation was doughy. The sensation of the pulp was the last to go. If on attempting to extract a tooth the patient protested, a wait of ten minutes would cause this protest to disappear. This showed that the nerve-fibres passing into the mental nerve which supplied the skin of the lip must be peripheral in the nerve bundle of the inferior alveolar nerve, and that they were the first to be anæsthetised. Nearer towards the centre there must be involved the nerve-fibres of the periodontal membrane and the bone, and in the centre there must be the axis-cylinder process going to the pulp, and sensation was restored in the inverse direction. That depended on the rate of diffusion of the local anæsthetic and its linking with the axis-cylinder process.

The Psychological Human Factor.

When trying to estimate some of the finer effects upon human beings one was brought so greatly into relation with the psychological factor that it was felt

better to experiment with frogs. He described the means adopted for ascertaining the dose of novocaine normal to the frog, various strengths being injected into frogs' right legs. Care had to be taken to inject in a direction away from the spinal cord, otherwise paralysis of the whole of the sacral nerves resulted, with hemiplegia of both legs. Using a 1½ per cent. solution of novocaine and adrenalin the frog recovered from a M 5 dose in one to one and a half hours, and that was comparable to the recovery time in the human; the dose for the frog was proportionately to the human much heavier. It was found that merely exposing the frog's heart and injecting saline did not interfere with its action. A dose of M 2 novocaine and adrenalin produced on the frog's heart very slight alteration. With a M 3 dose the heart was beginning to be slowed, and the force of the ventricular contraction was lessened. With M 5 of the same mixture the heart continued to beat at first with very little change, but later there were signs that the auricular contraction was beginning to fail. Fifteen minutes later there was found to be a great and progressing inhibition of the heart's action. It was necessary to do the dissections with care, otherwise the loss of blood would, of itself, cause some definite heart failure. The conclusion arrived at was that novocaine and adrenalin injections had a definitely depressive action on the frog's heart.

He next set out to determine whether the effects just referred to were due to the novocaine or to the adrenalin. Therefore novocaine alone was injected, and the heart beats dropped from 31 to 20, but it could not be said that the heart was seriously affected; M 5 of 1 in 50,000 adrenalin alone produced a slowing of the heart, the force of the ventricular contraction being reduced. With 1 in 20,000 solution there was a more definite slowing of the heart, with failure of its auricular contractions. Still, he had never seen a patient seriously ill from the injection of adrenalin alone, though he had on occasion used large doses of it; and the fact that it produced a quicker action of the anæsthetic and gave a deeper anæsthesia made it a very suitable drug for certain operations. He tried to find, however, whether there was a more suitable drug with which to combine adrenalin so as to minimise the effects which had been found to be due to it.

The Action of Caffeine and of Strychnine.

He tried caffeine in combination with novocaine and adrenalin and found that it failed to prevent their depressive effects, and it appeared to have no beneficial effect on the heart. Strychnine had been much recommended and widely used as a supposed antidote to novocaine and adrenalin, but he found in his experiments that it was powerless to stop threatened heart failure. Under an injection of M 5 novocaine and adrenalin with atropine the heart was seen to be contracting vigorously, hence his conclusion was that atropine was by far the best drug to combine with novocaine and adrenalin in order to prevent the effects of adrenalin poisoning. But a great objection to the use of atropine, from the dentist's standpoint, was that it caused a paralysis of the secretory function of the salivary glands, so resulting in a very dry mouth; indeed, this was so marked that it was deliberately used for operation in which this dryness was sought after. Prof. Pembury had suggested to him that the patient's discomfort from this dryness could be mitigated by giving him a little glycerine and rose water for the mouth until the restoration of the secretory function.

In the frogs used the best place for the injections appeared to be the muscles of the back; then one was sure of getting absorption into the connective tissue, and not into the blood-stream or the lymphatic spaces. He showed, by means of coloured fluids, the path of the fluids after injection, and, by micro-photographs, the distortion of muscle-fibres by the forcible introduction of the injecting needle. There were also thrown on to the screen numerous photographs of blood-films taken after injection, and of sections of kidneys. Clinical results he said he hoped to bring

forward, with further experimental data, in a future communication.

Discussion.

Mr. F. ST. J. STEADMAN praised this piece of work, and said he could confirm the results set out by careful observation on human patients. Of the definite action of adrenalin on the heart he had full evidence. If three "E" tablets (equalling 1/400th of a grain) of adrenalin were given, the patient nearly always complained of throbbing in the head and general illness four or five hours after the injection. This could be avoided by reducing the dose. He also felt strongly that the character of the glass used had much to do with the quality of the solution used. He thought the difference in the time for induction of anaesthesia was not always due to inaccurate injecting; there was the factor of personal idiosyncrasy. In some, the anaesthesia might pass off even before the completion of the operation.

Dr. ALEXANDER LIVINGSTONE expressed the hope that this valuable research would be continued, and the results so far obtained largely disseminated. He did not think the frog an ideal animal on which to base conclusions for guidance in the case of the human subject, and considered that it was desirable to regard the time factor in the frog as 1/16th that of the human. He asked whether the various experiments were performed under, as far as ascertainable, identical physical conditions, such as temperature, humidity, the presence or absence of draughts. It was clear that the dangerous drug in the series used was adrenalin.

Mr. COLIN KEAY asked whether potassium sulphate had been tried in place of Ringer's solution, as some workers claimed that it doubled the potency of the novocaine. Before the war the Germans suggested about 1/2 per cent. sodium chloride and 0.4 per cent. potassium sulphate being used, and claimed that this brought the potency of novocaine practically to that of cocaine. He thought more research along these lines would be valuable.

Reply.

Mr. DOUBLEDAY, in reply, repeated his conviction that in patients who showed susceptibility to novocaine poisoning the bad effect was due to the adrenalin, but in the dosages used by dentists he did not think it constituted a harmful factor. He could not solve the cause of delayed anaesthesia which some patients showed. He thought that in the case of a cold-blooded animal like the frog it easily acclimatised itself to the ordinary physical conditions of the laboratory. It had been suggested that acid sodium phosphate might be added to the anaesthetic solution so as to increase its hypotonicity.

A large number of tracings, graphs, and tables, as well as specimens of experimented frogs, supported the thesis, and the paper was preceded by elaborate experiments on the subject. A cordial vote of thanks to Mr. Doubleday for his contribution was accorded, on the motion of the PRESIDENT.

CHELSEA CLINICAL SOCIETY.

A MEETING of this Society was held at St. George's Hospital on Feb. 17th, Dr. GORDON LANE, the President, in the chair.

Sir THOMAS PARKINSON opened a discussion on

Diseases of the Climacteric in Both Sexes.

He drew attention to the changes that accompanied this period of life in men. Many men at this time of life showed changes in arterial tension with or without renal changes. He pointed out the uselessness of attempting to reduce the blood pressure in these cases by means of drugs, and said that alteration in the surroundings of the man, with lessened diet and rest in bed, were the chief assets in securing relief. In the female the flushings seen at the

climacteric were, he thought, due to the loss of ovarian secretion, and this loss upset the action of the thyroid and adrenals. At this period of life in both sexes the endocrine organs were very erratic. He considered the upset of the normal mental condition was due, in many cases, to the thyroid. The cause of the excessive headaches was possibly due to affections of the pituitary gland. It was most important that men should be treated before definite changes had been established in the vascular system. He thought that people of both sexes ate far too much at all periods of life, and that such excess was most harmful at this period of life.

Mr. A. RALPH THOMPSON put the age of the climacteric as from about 55 to 63 in the male. He showed that sepsis was more common in the male sex than in the female at about this time of life, and that the chief septic changes were associated with gangrenous or necrotic processes. With regard to the occurrence of growths of the bladder at this period of life, he thought that the practical side of this question was very different from that described in the textbooks. He also drew attention to the comparatively early age at which enlargement of the prostate gland gave rise to symptoms. He operated upon this condition, not so much for the mechanical obstruction that it produced, but because the enlargement so frequently led to disease of the kidney, especially of the nature of chronic interstitial nephritis. In his opinion, the general rule with regard to growth of the prostate should be the same as that occurring in other organs of the body, and he said that he had had several cases where malignant disease was found that had not been anticipated when the enlargement of the prostate was first diagnosed. He thought that to wait for fixity and irregularity of the large prostate was to put off any adequate treatment until too late, as these were symptoms of involvement of other organs.

The speaker then commented on certain clinical facts he had observed in connexion with cases of cancer of different parts of the body. He had noted the curious absence of bloom from the complexion of the face in cases of malignant disease, which he compared with the absence of bloom observed on the leaves of plants grown under calcium-free conditions. In his experience, the thyroid was enlarged in not a few cases. He gave figures showing that in malignant cases the thyroid was, on an average, of greater capacity by 6 c.cm. in malignant than in non-malignant cases of death. Some of the thyroids in malignant disease that had come under his view were very large. Acting on these observations he had been used to prescribe calcium and thyroid, and he gave an interesting account of some cases of inoperable carcinoma of the bladder, in which some success had been seen after this treatment. In some cases weight had been put on by the patients so treated. He concluded by bringing forward some cases in whom it appeared that the prostate gland might exert some influence upon the question of malignant disease in its neighbourhood. He thought cancer was a deficiency disease.

Dr. THEODORE HYSLOP pointed out that many men exhibited psychical symptoms at about the age of 50, and he thought that this was associated with the periodical holding up of uric acid in the system. He advocated saline purges for this condition with diaphoresis.

The PRESIDENT drew attention to the possibility of the patient having started life in a wrong manner. These initial errors were emphasised as the patient grew older. He agreed with Sir Thomas Parkinson about the diet being too great in many cases. He mentioned, in particular, arterio-sclerosis, chronic nephritis, and glycosuria as being the common diseases of this period of life.

Dr. ERNEST YOUNG, Mr. IVOR BACK, and Dr. ERIC PRITCHARD also addressed the meeting, and Sir THOMAS PARKINSON and Mr. THOMPSON briefly replied.

LISTERIAN SOCIETY.

A MEETING of this Society was held at King's College Hospital on Feb. 18th, Mr. C. P. G. WAKELEY being in the chair.

Dr. WATTS EDEN delivered a lecture on *Puerperal Sepsis in Relation to its Mortality and Preventive Treatment.*

Dr. Eden stated that during the last 13 years the general rate of puerperal mortality showed only a very inconsiderable improvement. There were three lines of defence: (1) Antenatal work; (2) efficient conduct of labour; and (3) early diagnosis and proper management of all cases of puerperal fever. With regard to the first, if this was efficiently done, vaginal examination after the commencement of labour in a straightforward case would seldom be necessary. It was regarded as an established fact that when puerperal sepsis occurred the cause was to be found, in the great majority of cases, in failure to achieve a surgically clean technique, the infection occurring during and not after labour. Referring to the "handy woman," so often called in by the poorer classes, the speaker said they were a definite source of sepsis to the lying-in woman, and until practitioners refused to work with such women the same conditions would exist. Notification of the disease had become a complete failure, and one eminent authority had gone so far as to say that in his district only 4 to 5 per cent. of cases were notified. This state of affairs was due to (1) uncertainty of diagnosis in the early stages; (2) reluctance of the doctor to expose his case; and (3) inadequate hospital provision for treatment.

In answering certain questions after the lecture Dr. Eden said that the vulva should always be shaved before applying forceps, but for a normal labour clipping the hair and applying iodine was sufficient. He did not recommend a rectal examination in place of a vaginal during labour, as this would be opening up another source of contamination.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Manchester on Jan. 16th, when Prof. A. DONALD, the retiring President, gave his valedictory address on the

Uterus as a Centre of Toxins and Irritative Products. Referring briefly to the toxæmias of pregnancy and of the puerperium, he said there were two conditions which were of special importance—namely, toxic liquor amnii and toxic lochia. He quoted a case of acute urticaria which was undoubtedly due to changes in the liquor amnii, and also referred to some cases of acute toxæmia coming on about the twelfth day of the puerperium, which were due to the accumulation of toxic lochia in a flabby uterus, the cavity of which was below the level of the cervix. There were cases, he thought, in which these toxic elements, produced during abortion or confinement, might persist for a long time afterwards, and referred to a case of acute eczema which occurred some months after an abortion and which resisted all treatment until the uterus was curetted and then rapidly and permanently vanished. These toxins, he believed, might in many cases affect the heart functionally and also the nervous system, and might play a part in causing rheumatic affections. Their origin was not only in the contents of the uterus, but sometimes in its substance. They were undoubted indications that fibroid tumours of the uterus were associated with a toxic condition in the patient. This was most noticeable when a fibroid was undergoing rapid diminution at the menopause. There seemed to be disintegration of the growth and absorption of the products into the general system, and this was attended by palpitation, profuse sweating, loss of flesh, and cachexia.

The cases he had referred to occurred mostly in parous women, but he believed that they were some-

times seen in nulliparæ and virgins. Under irritative products he included cases in which the effects seemed to be purely local. Sometimes these cases seemed to be the result of bacterial invasion and sometimes they seemed to be due entirely to chemical irritation, but it was not always easy to distinguish between them. The so-called senile vaginitis, and especially the cases associated with senile endometritis and pyometra, seemed to be caused by bacterial invasion. Pruritus was another condition which might be due to the same cause, but it also occurred in single women. In the latter case it seemed to be often due to irritative elements in the menstrual discharge or to an irritating leucorrhœa. Another condition which might possibly be often due to irritation was dyspareunia. In the very severe cases there was probably a nervous or even a mental element, but in the more common type he believed that a uterine discharge (which might be slight in amount) kept up a condition of local irritability. His practice was to dilate and curette in these cases, and the results had been more satisfactory than by any other method of treatment. Finally, he thought that cervical erosion was often the result of an irritating discharge from the uterine cavity. The general opinion seemed to be that it spread from below, and many seemed to think that it was most commonly caused by gonorrhœa. He thought that this cause was greatly exaggerated. The irritation might follow a confinement, but it was not uncommon in virgins. The teaching was largely that it was purely cervical in origin, but there were strong grounds for believing that it was caused by the discharge from the uterus. In all cases of cervical erosion, except where there were reasons to believe that it was the result of gonorrhœa, the cavity of the uterus should be curetted. It was not uncommon in these cases to remove by the curette large masses of glandular tissue. A condition which seemed to him to prove the irritative effect of an intra-uterine discharge was the so-called erosion of the posterior lip in cases of retroversion. The erosion was not confined to the posterior lip, as could be demonstrated by observation when the uterus was straightened by means of a vulsellum, but it was chiefly situated there because the intra-uterine discharge, owing to the position of the uterus, was obliged to flow over the posterior lip of the cervix.

Pelvic Adenomyoma.

The adjourned discussion on Dr. KENNETH V. BAILEY's paper on the Pathology of Ectopic Müllerianoma (pelvic adenomyoma), read at the meeting of the Society on Dec. 19th, 1924,¹ was then opened.

Mr. P. GOUGH thought the cell-implantation theory explained most satisfactorily many cases previously difficult to understand. He thought, however, there was still room for Cullen's mucosal theory and for the theory of development from Müllerian rests. He referred to a case he had recently seen of a tumour over the left pubic spine which became swollen and painful at each menstrual period, and at operation proved to be an adenomyoma of the round ligament. There was no evidence of any intra-pelvic disease and no hernial sac, so this tumour could not be accounted for by the implantation theory.

Mrs. BARTON HALL wondered whether retrograde menstruation was a pathological process as Dr. Bailey suggested and whether it was associated with other pathological changes, including an increase in the loss of surface epithelium. She asked why this actively invading epithelium did not embed itself in the wall of the vagina. She also asked as to the exciting cause and frequency of retrograde menstruation and if the growths described tended to become malignant.

Prof. W. E. FOTHERGILL wondered whether menstrual back flow was an isolated occurrence or took place repeatedly in certain women.

Miss M. H. F. IVENS had been able to excise localised

¹ See THE LANCET, Jan. 17th, p. 129.

uterine adenomyomata in one or two cases without removing the uterus.

Dr. DOUGAL thought that the evidence in favour of the Fallopian type of growth was not very convincing. It appeared to rest chiefly on the fact that the cells in these cases were ciliated, but the uterine cavity was also lined by ciliated epithelium, and he could not understand why menstrual hæmorrhage should be associated with the activity of tubal epithelium. Retrograde menstruation appeared to furnish the most reasonable explanation of how the implants reached the peritoneal cavity. Adenomyoma had been found in certain situations difficult to explain on this theory, but he thought that all of them could be so explained. He referred to the experiments on rabbits, successfully carried out by Victor Jacobson, proving that endometrial transplants in the peritoneal cavity were capable of active growth in the new situation. Clinical observations also supported this. The association of fibroids with adenomyoma had been frequently noted. He further referred to the confusion there was with regard to the nomenclature of this condition, and did not think Dr. Bailey had improved matters by suggesting another name. He thought the terms "endometrioma" and "endometriomyoma," suggested by Blair Bell, were the best so far.

Prof. BLAIR BELL being absent, his remarks were read by Dr. R. A. HENDRY. Prof. Blair Bell stated he had been so fortunate as to be present as a guest of the American Gynæcological Society on the historical occasion when Sampson read the first communication in which he demonstrated the endometrial character of the elements which were to be found in the ovaries in the circumstances under consideration. When Prof. Blair Bell returned home in possession of this knowledge he was able to discover endometrium in the ovaries in a case of bilateral "tarry cysts." This was the first case demonstrated and published in this country. He knew of no inherent reason why there should not be two types of ectopic gland-bearing tissue, one endometrial and the other of tubal origin, but it was only the endometriomata that had any practical or clinical interest, for menstruation could not occur in connexion with tubal glandular tissue. He thought that Dr. Bailey might be in error in describing the line of epithelium which he had illustrated on the surface of one ovary as tubal; it resembled germinal epithelium. Prof. Blair Bell held that in certain cases the "cellular spill and implantation theory" of Sampson could not apply. Endometriomyoma of the round ligament in the inguinal canal could not originate in this way. Such a tumour was congenital in nature, the endometrial tissue having been displaced by the external muscular coat of the uterus in the process of development. Prof. Blair Bell believed that endometriomata were both developmental and implantational in origin.

In his absence, Dr. HENDRY also read remarks for Dr. LEITH MURRAY, emphasising the need for keeping an open mind on the pathology, more particularly in view of the adhesions that occurred at certain sites, and the association in some cases of "adenomyoma" of the Fallopian tubes with the tubercle bacillus. Dr. Murray asked to what extent bilateral oöphorectomy influenced these ectopic growths when occurring, say, in the recto-vaginal space.

Reply.

Dr. BAILEY, in his reply, referred to mistakes made in the past as to the nature of this condition. He referred to the two views held with regard to the amount of epithelium lost from the endometrium during menstruation, and said that he believed that a considerable quantity was cast off into the uterine cavity during menstruation. The vaginal wall was often invaded to a certain extent by small nodules of growth. He had never found any trace of bacterial infection in these growths, and cultures from the chocolate fluid blood were always sterile. He had never observed a case exhibiting malignant change. He would like to emphasise that the invasion of the

ovary by the growth caused the formation of a cavity without any evidence of the formation of a cyst wall. He therefore thought that the term "tarry cyst" was wrong, and that "ovarian blood cavities" or "menstrual blood cavities of the ovary" should be substituted. The "site of rupture," he held, was merely the original site of implantation. He believed that the invading elements were deposited probably at every menstrual period in some women, but did not necessarily invade at every deposition. He also believed that retrograde menstruation was of regular occurrence and that it might be one of the great factors in the causation of dysmenorrhœa in young women.

Exhibition of Cases and Specimens.

Dr. DOUGAL showed a specimen of a very large "Tarry Cyst" of the Ovary which was removed from a married woman aged 30, who had never been pregnant. The cyst measured about 10 inches in diameter and had thin walls except where adherent to the broad ligament. Its inner surface had no definite epithelial lining, but appeared to be composed of a striated layer of fibrin-like material. Outside this the wall was composed of compressed ovarian tissue. The chief interest lay in the size of the tumour, whose contents measured about 2 pints. Tarry cysts varied much in size but were rarely larger than a tangerine. The largest one in Sampson's series of cases measured about 5 inches in diameter.

Prof. FOTHERGILL showed a *Hæmatometra* associated with absence of the vagina, double hæmatosalpinx and ovarian blood cysts removed from a young girl 11 years of age. When examined under an anæsthetic the vaginal orifice admitted only the tip of the little finger and the urethra was a mere slit. Rectal examination showed a very large uterus. At the operation it was found that the vagina was only represented by a fibrous cord.

Cases of hæmatometra associated with other developmental abnormalities were referred to by Mr. J. PHILLIPS, Dr. W. FLETCHER SHAW, Dr. HENDRY, and others.

Dr. J. W. BURNS read notes of a case of *Hydatidiform Mole and Chorio-epithelioma* from the same patient.

Dr. J. E. GEMMELL (Liverpool) was elected President of the Society for the ensuing year.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

At a meeting of this Society, held on Feb. 5th, Dr. PETER HOWIE in the chair, Prof. THEODORE SHENNAN read a paper on

Arterio-Venous Aneurysm in the Thorax.

The paper was based upon two cases in which Prof. Shennan had performed a post-mortem examination, and upon 72 other reported cases. After recalling the fact that William Hunter was the first to describe traumatic arterio-venous aneurysm and that James Syme was the first to describe spontaneous arterio-venous aneurysm, he proceeded to relate his two cases. In the first, perforation had occurred just below the azygos vein, and in the second, perforation had taken place into the right auricle just below the vena cava. The cedema, cyanosis, and distension of veins, limited to the upper part of the body, head, neck, and upper extremities, but descending lower on the back than on the front of the trunk, were then described, and the sharp contrast presented by the almost emaciated-looking lower part of the body was emphasised. In the first case a systolic bruit was heard over the situation of the aneurysm of the aorta, extending outwards from the aortic area. In the second a well-marked "bellows" murmur was heard in the aortic area. Death followed in the first case on the thirty-first day after the perforation occurred, and in the second about three weeks after the perforation. In both cases, at a post-mortem examination, well-marked syphilitic aortitis was found,

and in the second case the compression of the superior vena cava at its lower part had divided its lumen into two narrow channels.

In considering the whole subject on the basis of these two cases and the others culled from the literature, Prof. Shennan found that ten times as many males as females were affected, and chiefly between the ages of 40 and 60. A more or less definite history of syphilis was available in less than 40 per cent., but in only ten cases could syphilis be fairly reasonably excluded. The influence of a previous typhoid infection might have been important in three cases. In no case was any information given with regard to rheumatism. Seventeen cases were definitely alcoholic. A definite exciting cause of increased blood pressure was apparent in less than half the cases. In others the perforation occurred during the night, and in a considerable number the absence of strain was actually noted and commented upon. As a rule the onset of the swelling and cyanosis was stated to be sudden, but in at least six cases swelling had existed for some time before more severe symptoms developed, and this may have been the case in others. There was no pain at any time in eight cases. All, with three exceptions, suffered from severe dyspnoea, going on to orthopnoea. Perforations were found in the termination of the left innominate vein, at all parts of the superior vena cava, and in the upper part of the right auricle. The murmurs were continuous, or double or single systolic in cases in which perforation had occurred at any of these situations. In five cases there was no murmur at all. As to the swelling, it was shown that this depended more on the extent and degree of compression of the vena cava by the aneurysm than on the position of the perforation, though in some cases this was an important factor. No fewer than nine of the cases survived for a period of over two months, the duration varying from 11 weeks to 20 months, in five cases the duration being five months or over; and in one case—the only one in the series—there was apparent recovery.

The differential diagnosis from closure of the superior vena cava resulting from compression and thrombosis was not always easy, and sometimes seemed to be almost impossible. The severe oedema and cyanosis sharply limited to the upper half of the body anteriorly seemed to be more or less characteristic of varicose aneurysm, whereas in closure from compression and thrombosis such alterations might not be so extreme and did not develop so quickly because there was more opportunity for development of a collateral circulation; but the swelling in a few cases of compression had reached as high a grade as in the case of perforation. Moreover, the suddenness of development of the swelling was not absolutely pathognomonic because, occasionally, rapid thrombosis of the compressed superior vena cava—e.g., in dissecting aneurysm—might produce very similar signs. On the other hand, in Lichtheim's case of varicose aneurysm (*Deutsch. Med. Woch.*, 1905, xxxi., 207) the cyanosis and swelling developed slowly. The course of the illness was just as little diagnostic, as it might last only a few hours or many months. The venous pulsation in the neck was probably the best indication of a varicose aneurysm, but it was much more often absent than present, no doubt because of compression of the vein. As to the continuous blowing murmur which was so often described, this, as Prof. Shennan had shown, though an important sign, occurred in less than 50 per cent. of the cases, and, moreover, in a case reported by Dujardin-Beaumetz, in which there was almost complete closure of the superior vena cava resulting from compression of an aneurysm of the aorta, there was a continuous murmur. This, however, was not an important objection, because, as Prof. Shennan had already pointed out, other cases in which a similar pathological change was present showed a somewhat different murmur. One had to rest the diagnosis upon a combination of physical signs, seeing that even the absence of a murmur might not weigh greatly in the scale against the diagnosis of a varicose aneurysm.

Reviews and Notices of Books.

BACTERIOLOGY.

An Introduction to Practical Bacteriology. By T. J. MACKIE, M.D. Glasg., D.P.H. Oxf., Professor of Bacteriology, University of Edinburgh; and J. E. McCARTNEY, M.D., D.Sc. Edin., Lecturer in Bacteriology in the University. Edinburgh: E. and S. Livingstone. 1925. Pp. 297. 8s. 6d.

CURRENT bacteriological methods, including the preparation of media, the use of the microscope, staining methods, animal inoculation, and the main principles of bacteriological diagnosis are conveniently collected together in this handy volume. The methods advocated are for the most part tried and reliable ones. In certain instances the technique described does not conform to the most usual present-day bacteriological practice. For example, there is no mention of the use of boiled-blood media for the cultivation of *B. influenza*; so uncertain a criterion as mannite fermentation is recommended for the identification of the *Streptococcus faecalis*; sheep's heart extract is recommended for Wassermann antigen, and Wright's capsules for the collection of blood for the Widal test. Probably not many practising routine bacteriologists use Neisser's stain for the recognition of *B. diphtheriae*. The scope of the book is ambitious, such subjects as intracranial inoculation for the diagnosis of rabies and the diagnosis of plague infection in wild rats being included; these seem rather advanced exercises to be indicated in a book "prepared primarily for the use of students in the University of Edinburgh." Many a teacher of bacteriology feels that he has achieved much if, at the end of his course, the student can look Gram's stain in the face, firmly and without misgivings. Nevertheless, this is a useful laboratory guide and, on the whole, an exceedingly trustworthy one.

Principles of Bacteriology. Third edition. By ARTHUR A. EISENBERG, A.B., M.D., Director of Laboratories, St. John's Hospital; Pathologist to Lakewood Hospital; Serologist to St. Ann's Hospital, Cleveland, Ohio. London: Henry Kimpton. 1924. Pp. 216. 10s. 6d.

THIS little text-book is intended primarily for the use of nurses who, in America, so the author tells us in his preface, receive instruction in bacteriology during the first year of their training. The book should certainly supply all the bacteriological lore that the nurse has need of. The author seeks to assimilate both gnats and camels, and, while the nurse early in her career is enlightened by a picture of a man looking down a microscope—to show how the thing is done (Fig. 16)—by the time her course in bacteriology is ended she is expected to be sufficiently proficient to answer, for example, questions of following calibre (No. 26, p. 207): What is an amboceptor? Agglutinin? Precipitin? Bacteriolysin? Haemolysin? Phagocytosis? Opsonin? Leucocytosis? Complement? Weigert's Law? If thus is done to the nurses, what will be the lot of the Third M.B. student, such a one may well ask himself in horror! We ourselves do not find Weigert's Law easy to understand, and the index to Dr. Eisenberg's vade-mecum does not lead towards enlightenment. The contents of this book amply cover any field of bacterial knowledge which may be demanded of nurses; it is not suitable for medical students.

Handbook of Bacteriology. By JOSEPH W. BIGGER, M.D. Dub., F.R.C.P. Irel., D.P.H., Professor of Bacteriology, University of Dublin. London: Baillière, Tindall and Cox. 1925. Pp. 413. 12s. 6d.

THIS introductory text-book of bacteriology is an attempt to provide the medical student with a book that is smaller than those in current use, which,

the author complains, tend to drive him to the execrated but ever popular cram-books. We agree with Prof. Bigger that the advice to assimilate one of the standard text-books of pathology, such as "MacCullum" or "Muir," and at the same time to acquire a working knowledge of "Muir and Ritchie," is likely to suggest to the student, at the outset of his course in these important subjects, that the task set is beyond him. This little volume will, therefore, meet a definite need and is likely to have a large measure of popularity. The information conveyed is sound and sufficient and the illustrations, many of which are drawings by Dr. E. C. Smith, are good, although *B. coli* in Plate 3 looks very atypical. The author believes in teaching Ehrlich's conceptions and nomenclature of immunity, which he illustrates by rather unconventional diagrams: while we believe that nothing is lost to the student by omitting extremely hypothetical matter, which is apt to be looked upon as representative of material facts rather than as a scheme of illustration. In the section on streptococci the heat test for differentiation of the faecalis or enterococcus type is not mentioned, although it is generally agreed to be the most reliable single test available. We do not agree with Prof. Bigger's presentation of Bordet's views upon the action of the bacteriophage of d'Herelle. These, however, are minor points, and the book can confidently be recommended as accurate and adequate for the student's purpose.

OPHTHALMOLOGY.

Refraction of the Eye, including Elementary Physiological Optics. By CHARLES GOULDEN, O.B.E., M.D., F.R.C.S., Ophthalmic Surgeon to the London Hospital. London: J. and A. Churchill. 1925. With 180 illustrations. Pp. 276. 10s. 6d.

It is evident, says Sir John Parsons in his preface to this book, that a thorough knowledge of the principles of optics underlying the fundamental apparatus of vision is essential to a sound study of the subject. Mr. Goulden's book is written to supply this want, and from this point of view it will be found useful if not entirely successful. Thus an old stumbling-block for many is the difference between the principal points and the nodal points of the eyes. All books of this sort affect to explain this, but the practical significance of these mathematical abstractions is seldom rendered clear to the student weak in mathematics, and we do not find that Mr. Goulden has succeeded much better than his predecessors. On the other hand, the definitions of the angles α , γ , and κ , which have a practical importance in connexion with an apparent squint, are clear and to the point. The book, however, is by no means all mathematical, and we especially commend those parts of it which bear on the examination of patients. The chapters on ophthalmoscopy and retinoscopy are excellent. We do not remember, for instance, such a clear account elsewhere of the relative advantages of different positions of the source of light in retinoscopy for observing, on the one hand, the point of reversal, and, on the other, the band of light in astigmatism. The "scissors movement," too, a mystery to many, is well explained.

The book does not attempt to deal with the more general aspects of ophthalmic problems, such as the genesis of myopia or problems connected with binocular vision, but within its limits it is excellent. A few passages would bear revision in a second edition. On p. 130 the method of "fogging" the vision is recommended by means of either a convex or a concave glass, but surely, since the whole object of fogging is to eliminate the accommodation, the use of a concave glass is in most cases inadmissible. No doubt what is meant is, in myopic cases, to use a weaker concave glass than that which gives best vision, but this should be expressed. Again, on p. 133 the instructions for dealing with cases of anisometropia are not very intelligible, and the verbal construction is at fault. These, however, are

defects easily remedied when a new edition is called for, and we have no doubt that this opportunity will occur at an early date.

Diseases of the Eye. A Handbook of Ophthalmic Practice for Students and Practitioners. Tenth edition. By GEORGE E. DE SCHWEINITZ, M.D., &c., Professor of Ophthalmology in the University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1924. With 434 illustrations and seven coloured plates. Pp. 865. 50s.

THE revised edition of de Schweinitz's well-known text-book is well up to date. It is, of course, impossible for any text-book to keep pace with all the recent contributions to the theory and technique of a subject to which hundreds of workers in all civilised countries are constantly contributing their quota, to be found in specialist journals or proceedings of specialist societies. But good efforts are here made. For example, in the section on diseases of the cornea are reproductions of Holmes Spicer's diagrams illustrating the striate clearing of corneal opacities. We are grateful for these efforts, and do not complain that in the latest text-book there is no mention of Major Herbert's latest operation for iris inclusion in glaucoma, and no account of modern methods of testing for colour blindness; but a subject which is yearly, we may say monthly, absorbing in a greater degree the attention of ophthalmologists—the microscopical examination of the living eye with the help of the slit lamp—deserves more than a passing reference. An essential condition of a useful text-book, however, is that it should be limited to reasonable bulk. A readable summary of the authoritative knowledge existing at the date of publication,—that is all that is to be expected. This we do not fail to find in Prof. de Schweinitz's book. It would add still further to its utility if more references were given to the original papers of the vast number of authorities quoted in the text, so that a student desiring to probe any particular subject could do so easily.

The style is, as a rule, lucid, but there is still room for revision. Thus on p. 91 we read that according to Landolt the interval between fixation point and blind spot is greater in hyperopic than in myopic eyes, while a few lines further on we read that according to Hansell this average distance is almost identical in emmetropia and hyperopia, but in myopia is about 5 mm. (*sic*) greater. As the position of the blind spot has previously been defined in degrees this whole statement is calculated to confuse the reader. In the figures, the print, and the general get up of the book there is nothing wanting.

WILLIAM THOMPSON SEDGWICK.

A Pioneer of Public Health. By E. O. JORDAN and others. Yale University Press. London: Humphrey Milford, Oxford University Press. 1924. Pp. 193. 18s. 6d.

THIS book is published under the Williams Memorial Publication Fund, established in 1916 by a gift made to Yale University by Dr. G. C. F. Williams. The introduction is written by Sedgwick's wife and fully commemorates one who must have been a very charming man. Sedgwick was born at West Hartford, Conn., in 1855, graduated from the Sheffield Scientific School in 1877, and entered as a medical student at Yale University in the same year. His account of the medical school at that date reads like that of a mediæval school, inasmuch as medicine was apparently entirely taught from books and lectures, and anatomy was seemingly ignored. In 1879 Sedgwick and a friend of his were appointed to two vacant Fellowships in biology at Johns Hopkins University, and in 1883 he went to the Massachusetts Institute of Technology as assistant professor of biology. In 1888 he became consulting biologist to the State Board of Health of Massachusetts, and then began his life's work in sanitary science. A list of all the important offices which he filled connected with public

health will be found on p. 116, and the good influence which he exercised in America upon the foundation of public health theory and practice is evident throughout the book. The last chapter, which deals with Sedgwick's personal characteristics, gives a lively picture of an inspiring teacher and cheerful companion.

CHEMISTRY.

Dictionary of Applied Chemistry. Vol. V. Revised and enlarged edition. By Sir EDWARD THORPE, C.B., LL.D., F.R.S. London: Longmans, Green and Co. 1924. Pp. 702. 60s.

THE fifth volume of this monumental work starts with "Oxygen" and ends with "Rye." The high level of excellence is well maintained in this volume. A number of the articles will appeal to the medical man; amongst these may be mentioned photosynthesis by Prof. E. C. Baly, an investigator whose work has claimed much attention during the last few months. Prof. G. Barger deals in a lucid and readable manner with pepsin, the pituitary body, and putrefaction bases. Mr. K. S. Murray contributes an article on oxygen and its manufacture, and Prof. Sir W. Bragg one on radiology. A remarkably interesting article extending over 50 pages on photography is written by Mr. C. W. Gamble. This issue sadly synchronises with the death of Sir Edward Thorpe.

Qualitative Chemical Analysis. Fourth edition. By H. W. SCHIMPF, Ph.G., M.D. Revised by A. I. CONE, Pharm.D., Ph.G. London: Chapman and Hall. 1924. Pp. 201. 8s. 6d.

THIS work is based on lecture notes and laboratory exercises delivered to students at the Brooklyn College of Pharmacy. The author has endeavoured to compress into a small book most of the inorganic and organic qualitative reactions that a student of pharmacy is required to know. After dealing with elementary principles the analytical reactions of the metals and acids of pharmaceutical interest receive attention. The third part of the book is concerned with qualitative organic studies, and includes tests for official alkaloids and synthetic compounds as well as other organic substances used in medicine; also schemes for the detection of poisons and the analysis of some. The method of arrangement is logical and the diction concise. The section dealing with the qualitative analysis of organic substances is especially good, and should be of use to medical and pharmaceutical students in this country.

The Constituents of Coal-Tar. By PERCY E. SPIELMANN, Ph.D., B.Sc., F.I.C. London: Longmans, Green and Co. 1924. Pp. 219. 12s. 6d.

THIS book, one of a series of monographs on industrial chemistry edited by Sir Edward Thorpe, is mainly intended for the use of chemists who are interested in the individual substances which together constitute the material known as coal-tar. Tar is generally regarded as the source of a series of fractions possessing varying commercial values, and the fact that it consists of a number of chemical entities is frequently overlooked. The bodies obtained from tar are here divided into the general classes hydrocarbons, oxygen, sulphur and nitrogen compounds, the physical constants, preparation, properties, and reactions of each being recorded. The subject-matter of the volume is admirably arranged and well printed.

SKILL IN WORK AND PLAY.

By T. H. PEAR, M.A., B.Sc., Professor of Psychology in the University of Manchester; Fellow of King's College, London. London: Methuen and Co. 1924. Pp. 107. 4s.

THE study of methods of scholastic instruction has become the elaborate science of pedagogy. Instruction in games and martial exercises has been almost equally discussed, except perhaps in its theoretical

aspect, but the methods of teaching people how to work, and even the selection of those who should teach, have been left to rule of thumb. This hindrance to industrial efficiency is being attacked by the Institute of Industrial Psychology and the Industrial Fatigue Board. Prof. Pear, more versatile than an official body, takes advantage of the peculiar phenomenon that in our country there are probably a greater number of teachers of games than of manual work, and that in some sports there is a technical language describing the muscular movements involved. He then combines the study of work and play in such manner that the swing of a golf club or of a miner's pick becomes of equal interest to the reader—provided, of course, that the latter is not biased by any predilection. The author's aim is to help those who would bring order into haphazard industrial training, and in this he succeeds. The laboratory psychologist and the student of human motives and temperament are often remote from each other; Prof. Pear combines the outlook and experience of both, and the happy result is a suggestive and useful book.

JOURNALS.

BOLETIN DEL INSTITUTO DE MEDICINA. Experimental para el Estudio y Tratamiento del Cancer. University de Buenos Aires.—The first number of this Bulletin, published August, 1924, contains two articles only, both by the Director, Dr. Angel H. Roffo, one on hydatid cysts produced experimentally in the brain and the other on the infectious sarcoma of fowls. The first article is concerned mainly with the locality and development of hydatid cysts after injection of infective material directly into the brain substance of rabbits. It brings out some points of interest, but is only remotely related to the problem of cancer. The second paper illustrates the growth of the round-celled sarcoma in fowls and its metastases. The first inoculation was made with material from another growth in the form of dry powder, and the remainder from a solution of the growth so produced in Ringer's fluid. The tumour develops very rapidly, is at its maximum in four weeks, and soon causes secondary deposits, most frequently in the lungs and liver. Both papers are copiously illustrated and the illustrations, on the whole, are good, the whole production being creditable to the University Press of Buenos Aires, from which it is issued, while its contents give ground for hoping that valuable work may be done in the future by this new experimental laboratory.

New Inventions.

AN ANAL SPECULUM.

THE accompanying illustration of a small anal speculum which is especially useful for the injection

treatment of piles is sufficiently descriptive. The bulb on the end of the speculum renders it self-retaining so that the operator has both his hands free.

Messrs. Arnold and Sons (John Bell and Croyden, Ltd.), 50-52, Wigmore-street, London, are the manufacturers.

HAROLD BURROWS, M.B.,

THE LANCET.

LONDON: SATURDAY, FEBRUARY 28, 1925.

PRESERVATIVES IN FOODS.

THE draft regulations¹ designed to give effect to the majority of the recommendations of the Departmental Committee on the Use of Preservatives and Colouring Matter in Food have been issued. Their general purport is the abolition of the use of formaldehyde, boric acid, and salicylic acid in food, and the permission of the addition of limited proportions either of sulphur dioxide and benzoic acid to certain specified articles of food, which must be labelled as containing preservatives. Colouring matter containing antimony, arsenic, cadmium, chromium, copper, mercury, lead, or zinc is forbidden, as are certain vegetable and coal-tar colours. No thickening substance, other than sugar, is to be added to cream. Representations on the draft regulations may be sent to the Ministry of Health within a period of 40 days from the date of their issue, and it may be anticipated from the controversy which has been aroused that representations will not be wanting. It is the proposed prohibition of boric acid and its compounds that will probably meet with most opposition, for it is contended by many authorities that is unnecessary and undesirable. The grounds advanced in favour of the borates are that adequate scientific evidence has not been disclosed that they are harmful when used as preservatives, while their rejection may lead to a great increase in the cost of foods hitherto so preserved, and an increase in the use of decomposed food. It is all to the good that such distinguished authorities as Sir WILLIAM POPE, Prof. F. W. TUNNICLIFFE, and Dr. ROBERT HUTCHISON have ventilated this question, since its importance is obvious, and it is highly desirable that any legislative action following this report should be based upon scientifically ascertained facts and not upon prejudice. At the same time the subject is so important to public health that it will be a pity if a controversy develops as to the merits or demerits of particular preservatives which will obscure the fundamental principles in question.

There are certain factors in the problem upon which medical men, at any rate, should be able to come to an agreement. The first of these is that the present position in regard to preservatives in food is an intolerable one, intolerable alike to the food manufacturer, the local authority, and the consumer. The former does not know where he stands and is prejudiced by unfair competition; the local authorities have no standards to guide them in taking legal action—moreover, separate actions in the court are wasteful and expensive; the consumers are, all unwittingly, obliged to consume a considerable proportion of their food mixed with chemicals which may be harmful, and as they do not know if they are there or not they cannot decline to buy such food. The second factor is that the basis of action advocated by the 1924 Departmental Committee is the only practicable one. This is the prohibition of all preservatives in foods except those definitely permitted. Prof. TUNNICLIFFE has suggested in the *Times* that legislation should follow on the lines of the

recommendations of the 1900 Committee. The form of these recommendations, however, is regarded as thoroughly unsound by many authorities on public health; it appears only to tinker with the subject. They merely recommend that particular preservatives in certain foods should be permitted and certain others should not. It is surely futile to prohibit named preservatives, since the trade chemist will always be able to find new ones to replace them. It is a conspicuous merit of the 1924 Committee report that they recognise this fact. Dr. W. SAVAGE² puts this point clearly; he says: "The attitude should be that all preservatives must be prohibited until sanctioned, and the State, as represented by its Health Ministry, should be courageous enough to make up its mind which to sanction, while being at the same time, on the one hand, always ready to withdraw its consent if the accumulated scientific data, which should be available and utilised as the result of that sanction, proves that any preservative is prejudicial, and on the other hand ready to admit the use of others which scientific evidence shows to be without detriment." A third matter on which there should be agreement is that the name of the preservative and the amount added should be declared.

Assuming that these fundamental principles are agreed upon, there remain two questions which are clearly highly controversial. The first is as to whether any drastic prohibition of preservatives will make matters worse by restricting supplies and so enhancing their cost—leading to the consumption of decomposed food, while the second is the choice of the preservatives to be put on the permitted list. It is curious the insistence with which the increased cost argument turns up whenever a public health reform is involved. The opponents of clean milk insistently plead that if milk is obtained reasonably clean it will cost much more and be prohibitive in price and the last state be worse than the first. A similar argument was raised against the use of chemical preservatives in milk. The argument fails to take into consideration that preservatives are not only added to sound perishable articles to maintain their soundness, but are frequently added to foods which can perfectly well be kept fresh sufficiently long without their addition if cleanliness is maintained in preparation and handling. These preservatives are a direct substitute for cleanliness. The more the matter is investigated the fewer appear to be the foods for which preservatives are necessary, but that there are cases for their legitimate addition is the reason for a schedule of permitted preservatives. The suggestion that the restriction of preservatives will cause more decomposed food to be eaten, and in consequence a great increase in cases of food poisoning, is based upon the view that such food is a cause of food poisoning, a conception which does not appear to have any evidence in its favour. As we pointed out last week, the large majority of cases of food poisoning are traceable to the *Salmonella* group of bacteria, and no authenticated case of food poisoning due to the consumption of decomposed food is on record.

The choice of the preservatives to be scheduled as permitted, the amounts to be allowed, and the foods in which they are to be introduced form one of the most difficult problems connected with food preservation. Borates are rejected by the recommendations of the 1924 Departmental Committee and prohibited in the draft regulations. By some authorities, however, they are advocated as preferable to sulphites which it is proposed to allow in certain foods. It must be

¹ Draft, dated Feb. 17th, 1925, of the Public Health (Preservatives, &c., in Food) Regulations, 1925, proposed to be made by the Minister of Health. H.M. Stationery Office. 2d.

² Food Poisoning and Food Infections. Cambridge University Press. 1920. P. 214.

conceded that much of the evidence so far offered is unsatisfactory. It is desirable that the evidence given to the Departmental Committee which enabled them to state "we are nevertheless convinced that the prohibition of boric acid as a food preservative in force in many countries is justified" should be made generally available. Without that evidence it is not profitable to argue the respective demerits of these two groups of preservatives. But although the exact form in which regulations should be framed is not a matter on which general agreement can be expected, the fundamental principles which guided the recommendations of the 1924 Committee must be accepted as sound, and the profession as a whole will probably find little to complain of in the way in which the Ministry of Health is setting out to attack this complicated problem.

THE FUTURE OF MEDICINE IN INDIA.

THE report of the Royal Commission on the Superior Civil Services in India, referred to as the Lee Commission, has already been summarised in these columns as far as it affected the medical services in this country.¹ According to the statement of the Under Secretary of State for India during the last session of Parliament, "no decision has yet been reached on the recommendations of the Lee Commission as to the organisation of medical services in India," and the whole matter "is still under consideration." While this state of affairs exists there is bound to be widespread discussion and criticism of the recommendations, and as the publications and pronouncements on this subject grow more abundant it becomes increasingly difficult to relegate all prejudice to the background and face both the facts of the present situation and the future in India under the reforms which have become "the law of the land." Under existing conditions the members of the medical profession working in India belong to the following groups: the Royal Army Medical Corps working with the British troops; the Indian Medical Service, working partly with the Indian troops, but for the most part employed in civil duties; graduates of the Indian universities and members of the Indian Medical Department, consisting of "assistant surgeons," formerly styled apothecaries, who hold junior posts in British hospitals; and "sub-assistant surgeons," formerly "hospital assistants," serving with the Indian troops, and not to be confused with the civil sub-assistant surgeons, who form yet another class. The Lee Commission, it will be remembered, recommended with regard to the Indian Medical Service that no attempt should be made to perpetuate that Service as at present constituted, and that the medical needs of both the British and Indian armies in India should be provided by the Royal Army Medical Corps (India), which should absorb the Indian Medical Service. With regard to the needs of the civil population, it was recommended that a Civil Medical Service should be constituted on a provincial basis, and that entrance to this service should be regulated by a competitive examination. A minimum number of British officers would be maintained in this Civil Medical Service, this number being under direct control of the Secretary of State, and in the event of the number not being obtained by the local government, officers of the Royal Army Medical Corps (India) would be seconded for service in the civil department.

The critics of the recommendations of the Lee Commission thus briefly summarised can roughly be divided into those who consider that the proposals

are too sweeping, and those who consider that they are not sweeping enough. Both sides in the discussion are bound to recognise that some change is desirable. The difficulties arising from two separate organisations, both concerned with the medical care of the troops, became apparent in the late war, when officers of the Royal Army Medical Corps and the Indian Medical Service had to work side by side. The new political outlook of India towards self-government to be reached in a gradual manner with a diminishing number of Europeans in the various civil services makes some change in the medical services an obvious necessity. From both the military and the civil points of view, therefore, some reforms are bound to take place. Major-General Sir GERALD GIFFARD, in a recent address before the East India Association,² considered that the Lee Commission had not gone far enough; he wished that the recommendations had been aimed at the closing and ending of all the medical services in India. He went on to state that "just as no country can hope to attain self-government and dominion status unless and until it can be responsible for its own law and order, and its own defence, so, in my opinion, no country can have a real medical profession until and unless it ceases to have the greatest part of its doctors in the Government services." Sir GERALD GIFFARD urges that medical education is the key to the situation. He holds that a medical college education in India should be complete in itself; that the curriculum of the existing colleges should be improved so that the degrees obtained have the approval of the General Medical Council, and that the admittedly imperfect and partial medical education of the Government medical schools—i.e., sub-assistant surgeon grade schools—should cease. He wants to see an independent medical profession properly educated and trained to carry on the work and traditions of the Indian Medical Service. The opinions expressed in the discussion which followed Sir GERALD GIFFARD's address were not entirely unfavourable to his proposals. It was agreed that there was an urgent necessity for raising the standard of the qualifications and degrees in India to the level existing in England, but at the same time there was a strong plea for the retention of the sub-assistant surgeon grade, which, although imperfectly trained, apparently does much useful work. The other side of the question is set out in a representation submitted to the Secretary of State for India by the Anglo-India Association, London, which voices the opinions of those who believe that the Lee Commission has gone too far. It is considered that from an administrative point of view the proposals raise many difficulties. Some definite unification of the military and civil medical services along the lines of the recommendation of the Verney-Lovett Committee (1919), as to the formation of an Indian Medical Corps are discussed, and the conclusions of the Esher Committee (1919-1920) are put forward to show that such an amalgamation of the two services is impracticable under existing conditions, and that therefore a continuance of the Indian Medical Service is desirable. If, however, a unification of the two services was deemed essential to any future scheme, then it is contended it should take place along the lines of the recommendations of the Medical Services Committee (Verney-Lovett, 1919) towards the formation of an Indian Medical Corps to discharge all medical duties in India, civil and military.

Between these two opposing views there is a middle course along lines suggested by the Lee Commission. From the military side the difficulty of the provision

¹ THE LANCET, 1924, i., 1114.

² Asiatic Review, January, 1925.

of an adequate reserve has been raised. This seems to be met by a minute by Sir REGINALD CRADDOCK upon certain of the conclusions of the Commission. If sufficient British medical officers are forthcoming for the proposed Civil Medical Service the problem is settled, "but if not, the Royal Army Medical Corps (India) will either be asked to increase its reserve to make up the deficiency, or the Secretary of State will have to make it good by special recruitment and on terms which will ensure the supply." The scheme for the provision of a Royal Army Medical Corps (India) was proposed and elaborated by Sir CHARLES BURTHAELL, late Director of the Medical Services, and from the military side this force will practically be the Indian Medical Service in another form without, it may be hoped, the old jealousies and frictions. Sir PATRICK HEHIR, writing in *THE LANCET* (1924, ii., 633), stated that "it may confidently be expected that a good number of well-qualified young men of the home medical schools desiring an Indian career will join this service with a view to obtaining professional work in the provinces, and when political opinion has settled down they will have a full and useful life." So much for the military side; from the civil point of view it has been strongly urged that all European members of the services in India have a right to attention by European doctors. This is met by the Lee Commission, who recommend the grouping of the districts of a province so that a British medical officer (civil or military) is posted to one station in each group with special arrangements for Europeans at any distance from the station. Any objections to the Lee Commission's proposals on this point are therefore without foundation. Pending any decision on the recommendations a limited number of European officers are being recruited for the Indian Medical Service on special terms. The dangers of considering this service as a permanent career by Europeans are obvious enough, but it does not follow that these temporary posts, which are being offered in attractive terms, will fail to give valuable experience to a man who is prepared to go abroad for a period at any rate before settling in consulting or general practice. The new policy in India is directed towards the progressive realisation of responsible government. The progress is bound to be slow and gradual, and it seems logical that the changes in the medical services should also be slow and gradual. If the general standard of medical education in India is to be raised, it will be some years before there is a body of adequately trained Indian medical practitioners to take part in the Indianisation of the medical services; but that this will ultimately result in medical as well as other services is regarded as inevitable by those familiar with the political outlook in that country.

SOME GREAT NAMES IN FRENCH MEDICINE.

IN the history of a nation one finds but a small place assigned to medical discoverers and discoveries. Prof. René Cruchet, of Bordeaux, in a lecture delivered to the Institut Français du Royaume Uni on Feb. 20th, commented on this and explained it as being due not to ingratitude on the part of the historian, but to the fact that a doctor's skill did not outlive the body it was practised on, and thus his work had of necessity an impermanent quality which was not shared with the products of the sculptor, the writer, or the artist. Prof. Cruchet gave an interesting summary of the development of the healing art from its earliest beginnings in France. It was in 1220 that the first French Faculty of Medicine at Montpellier was officially recognised by Cardinal Conrad, and

although, as Prof. Cruchet himself pointed out, France has contributed less to medicine itself than she has to the other arts and sciences, from that time onwards she has produced a succession of great medical men. The earliest great name in French medicine is that of Guy de Chauliac, the father of French surgery, who in 1363 published a book on Surgery which for four centuries was a bible for his successors in that craft. Chauliac operated on hernias, removed cataracts, and advocated extension in the treatment of a fractured femur. Under the influence of Guy de Chauliac the Montpellier Faculty of Medicine remained pre-eminent during the fifteenth century, a century which was harassed by epidemics of plague, typhus, "ergot gangrene," and leprosy. From 1376, by royal edict, the professors of that school were permitted to hold practical demonstrations in anatomy on the dead bodies of criminals. It was not until 1498 that the same privilege was accorded to the Faculty of Paris.

About 1540 Vesalius published his work on the Structure of the Human Body after several years' study at Montpellier. There he had as his teacher one Rondelet, who, if he have no other claim to immortality, has been pictured for ever in the character of Rondibilis by Rabelais, who was his pupil. Among the friends and pupils of Rondelet was a group of men, Platter, Lobel, Delécluse, and Bauhin, whom Linnaeus called the fathers of botany, and who were the forerunners of the genius of Boerhaave. The sixteenth century may be called the century of contagious diseases, and among the names of those physicians of that date are Houllier, Frenel, physician to Henry II., and William Vaillau, who helped to differentiate various types of epidemic fever. Vaillau, in particular, separated small-pox from measles, and left a graphic record of the characteristic symptoms of the onset of the latter disease. He also gave the first description in 1578 of whooping-cough, which he called Tussis quinta or quintana. But the outstanding figure of the sixteenth century is Ambroise Paré (1517-1590), of Laval, who laid the foundation of modern surgery. While according due homage to the teachers of the old world, he nevertheless was imbued with the new spirit of learning, which so marked the renaissance. The century of Louis XIV., the seventeenth, had no distinguished name in French medicine, for the whole art in France was overshadowed by the works of Harvey and Sydenham in England, but it would not be fair to take Molière's estimate of contemporary medicine as altogether a just one. In 1651 Jean Pecquet discovered the lymphatic circulation, and a little later Mauriceau wrote a treatise on Obstetrics, which may be considered as the first valuable work which had appeared on this subject. In the eighteenth century medicine broke away from the dogmatic conceptions which had dominated it in the preceding 100 years. The great scientific movement had begun which was going to transform the whole of man's outlook towards the body. Two names stand out, those of Théophile de Borde and De Barthez, who were forerunners in France of the return to the Hippocratic spirit of clinical observation.

With the nineteenth century biology became a science, and in turn was forged into a weapon for the fight against disease. Bichat (1771-1802), inspired by Borde, first described the different kinds of animal tissues, and following him came the period of experimental medicine, the discovery of physiological functions, the work of Magendie and Claude Bernard. Claude Bernard studied the action of poisons on living tissues and concluded that diseases acted on the body as poisons, but at the time of his death in 1878, Pasteur had already shown by inoculation that anthrax was caused by the anthrax bacillus. This was the beginning of the microbic theory of disease. Physics and chemistry also paid their tribute to medicine in the hands of Duchenne and Mme. Curie. How many of the great names of nineteenth century medicine in France are familiar to us? Baudelocque in obstetrics, Laënnec, Trousseau, and Charcot in

medicine, Dupuytren, Nélaton, and Terrier in surgery, Pinel and Esquirol the pioneers of the humane treatment of the insane, among others. Of our own medical leaders, one doubts if the list of familiar names would be much longer. Medicine triumphs in the present, for as Dr. Cruchet says, it is a living thing, and cares little about its own ancestry.

Annotations.

"Ne quid nimis."

HEXYL RESORCINOL AS A URINARY ANTISEPTIC.

URINARY infections, particularly pyelitis, provide one of the most trying problems in treatment. The majority of those who have to deal with them are willing to acknowledge that this field of therapy admits of wide improvement. Up to the present no drug administered by the mouth can be relied on to cure a chronic pyelitis, still less a chronic pyelonephritis, and the topical application of lavage is admittedly of limited usefulness. For this reason the announcement of the discovery of a new urinary antiseptic of great potency by a worker in Johns Hopkins University, Baltimore, has aroused interest. The drug referred to is "Hexyl Resorcinol," having the formula—

An account of the properties of the drug was given towards the end of last year by Veader Leonard.¹ The starting-point of Leonard's investigations was the synthesis of certain of the lower homologues of a series of alkyl resorcinols by Johnson² and his co-workers in 1913. It was found that the successive addition of carbon atoms to the alkyl chain was followed by a pronounced increase in bactericidal properties, and a coincident diminution in toxicity to experimental animals. Hexyl resorcinol is claimed to fulfil all the experimental qualifications of the ideal urinary antiseptic—viz., it is chemically stable, non-toxic, and non-irritating to the urinary tract, it has an antiseptic action in high dilutions in urine of any reaction, and is eliminated in high percentage by the kidney. In addition it is said to be actively bactericidal. It is found, however, that in human urine the drug is not infrequently secreted as a conjugate, and that this leads to a loss of the bactericidal action in the urine. Nevertheless, even in patients who apparently conjugate hexyl resorcinol very completely, the difficulty can be got over by regular administration over several consecutive days. One other point seems of importance—viz., that the simultaneous exhibition of sodium bicarbonate also destroys the bactericidal properties of the urine, not apparently because it makes the urine alkaline, but perhaps because it in some way facilitates the complete conjugation of the drug. It is disappointing, and detracts considerably from the interest and value of the paper that no clinical results are given by Leonard. He does sum up generally results of treatment in human patients, but no detailed account is presented. He claims that all the coccal infections of the urinary tract

clear up rapidly under hexyl resorcinol and without any other treatment. In coliform infections when the bacterial count is low, his drug is efficacious; when the count is high, disinfection is not obtained without adjuvant local treatment, and even then persistent treatment is necessary. And when the infection has spread below the surface of the mucous membrane the treatment is of no avail at all. Frank Kidd⁴ has pointed out, and none will gainsay him, that of all renal infections probably about 70 per cent. are coliform. He reports 140 cases of pyelitis in which 117 were infected by *Bacillus coli*. It is just the infections by coliforms which Leonard admits are least influenced by hexyl resorcinol, and his remarks on his results in coli infections might really have been written by any other writer about any other urinary antiseptic. Doubtless in the laboratory hexyl resorcinol is a powerful bactericide and an admirable antiseptic, but the human body is not a glass test-tube on a laboratory bench. The usual problem confronting the surgeon in these cases is that of a patient who has had a *Bacillus coli* pyelitis for a long time; nothing has so far brought about any improvement, and the patient grows tired of the whole business. Hexyl resorcinol may help here, and it should certainly be tried, for while the author does not claim that it is the last word in the treatment of all urinary infections, he does put forward strong claims for serious experimental trial.

AN INTERESTING RETROSPECT.⁵

George Sterling Ryerson, who has just published an interesting account of his strenuous life, came of an old Dutch family which first settled in New Amsterdam, the New York of to-day, in 1647. During the Revolution of 1775 the family were divided, and on the conclusion of peace the Loyalist members migrated to Canada. The writer of the book now before us was born in 1858 (p. 20) or 1855 (p. 32), being the only child of his father's third wife. He studied medicine in Toronto, Edinburgh, and Paris, and later in Austria and Germany, so that when he started practice in Toronto in 1880 he had an unusually cosmopolitan outlook. He served as a youthful private in the Queen's Own Rifles in the Fenian Raid, and as a surgeon with the Royal Grenadiers during the North-West Rebellion of 1885. In 1892 he gained a seat in the Ontario Legislature, and in the same year began his long struggle for the reform of the Militia Medical Service. In 1895 he organised the St. John Ambulance Association in Canada, and in 1896 established a branch of the Red Cross in Canada. For all his services in ambulance and army medical service work we must refer readers to the book itself, as well as for his accounts of the Boer War and the late war. In this latter struggle he not only gave his own work, but he also lost his son, killed at St. Julien, and his wife in the torpedoing of the *Lusitania*. The book is a record of good work unassumingly performed; but it is marred by errors which might easily have been corrected. The author says on p. 100 that the Order of St. John of Jerusalem was founded by Peter the Hermit at Jerusalem in 1030, having its origin "in the necessity for medical aid during the Crusades." Now the first Crusade started in 1095. It is true that there was a hospital in Jerusalem dedicated to St. John the Almoner, Patriarch of Alexandria, founded sometime before the recovery of the Holy Land by Godfrey, but Peter the Hermit did not visit the Holy Land until about 1094. After Godfrey had captured Jerusalem the dedication of the hospital was changed from St. John the Almoner to St. John Baptist and the society was organised as an Order in 1118. The curious thing is that Dr. Ryerson gives as his authority for his

⁵ Looking Backward. By Major-General G. S. Ryerson, M.D., C.M., Canadian Army Medical Services. Toronto: The Ryerson Press, 1924. Pp. 263. \$2.50.

statement Bedford and Holbeche's Order of St. John of Jerusalem, which says nothing about Peter the Hermit. Those who wish to investigate further will find an account of the rise of the hospital and Order in the *Evagatorium* of Felix Fabri, vol. ii., pp. 246 and 274 of Hassler's edition, 1843. Dr. Ryerson's memory has misled him when on p. 129 he speaks of Granada Cathedral being Gothic. As a matter of fact the building is a weak example of Græco-Roman style and the *trascoro*—i.e., the west end of the choir—is in the peculiarly offensive style known as churrigueresque, from the architect Churriguera. The Capilla de los Reyes, however, is Gothic. The presence of such errors should not deter anyone from reading this book, which is full of interesting matter.

THE CONTROL OF HOOKWORM DISEASE.

FOR the last four years an American Commission has been at work in the West Indies and South America on the essential problems of hookworm control and possible eradication. During this time many valuable investigations have been undertaken, and over 33 reports on the work accomplished have been published in the *American Journal of Hygiene*. The thirty-fourth report, which has recently appeared, and summarises the previous ones, is by Dr. W. W. Cort, who is well known as one of the most active workers in this branch of medicine, while he has also been responsible for formulating the general scheme of prevention and research. One detects in this report no unwarranted claim that the problem of hookworm prevention has been finally solved; indeed, the opinion is expressed that further intensive researches by numerous investigators are still necessary before a complete knowledge of the life-cycle of the ankylostome is obtained and the prevention of the disease thereby placed on an entirely satisfactory scientific basis. Dr. Cort and his colleagues have especially concerned themselves with the practical sanitary aspects of the problem. They have endeavoured to ascertain the complete story of the cycle of the larval ankylostome in the soil up to the point when it is capable of reinfecting man. The part played by domestic animals, especially fowls and pigs, in the dissemination of the disease has received especial attention, and a new species of hookworm has been discovered in the pig. Up till comparatively recently it has been considered that larvae in infected faeces could be exterminated by being buried deeply in the soil; unfortunately, however, this idea has proved to be fallacious; the larvae are able to migrate in a vertical direction from great depths in the soil, especially when it is of a sandy or loamy character.

The outstanding difficulty in the prophylaxis of hookworm disease in a primitive community is really a question of administration, discipline, and education. The natural habits of the people have become so deeply ingrained that it is impossible to change them in a short space of time, and undoubtedly it is this factor which has hitherto proved to be the stumbling-block of every well-organised attempt at hookworm eradication. The prevention of promiscuous defæcation in suitable soil cannot be accomplished, and it is now known that such soil remains infective for a considerable length of time. This difficulty existed in the former European outbreaks of ankylostomiasis, and it is therefore no matter of surprise that in South America it is no easier to solve. The thirty-fourth report of the Rockefeller Commission marks the end of its labours in the West Indies, but certain lines of investigation, which are indicated, continue to receive the attention of various workers. The reward of the Commission's labours may at present appear to be a small one, as the professed object has not been entirely attained, but we have no doubt that largely as a result of the Rockefeller work it eventually will be. From the economic point of view hookworm disease has, during the last 50 years, caused practi-

cally incalculable economic loss, though the remedy appears to be so simple. It is a matter solely of simple sanitation and one capable of achievement if only the sufferers can be induced to realise the importance of rudimentary hygiene. But who is there who will point a finger at the habits of the American "poor white" or ignorant negro when there exist in our own enlightened country evils almost as gross, in the shape of "privy middens" and "stable dumps," which are still permitted to exist in the centre of some of our larger towns.

THE FELLOWSHIP OF THE ROYAL SOCIETY.

ALL the names recommended for election to the Fellowship of the Royal Society are of moment to those who are watching the progress of modern medicine, since practically all the sciences have been enlisted in its service. Especial interest, however, attaches to the choice, year by year, of Fellows from among those who are devoting their lives to the direct study of the structure and function, whether normal or pathological, of the human body, and of the diseases to which it is liable. Physiology is honoured this year in the person of Dr. C. Lovatt Evans, professor of physiology at St. Bartholomew's Hospital Medical College, whose work on the hydrogen-ion concentration of body fluids and on the utilisation of sugar by the heart has had a profound bearing on our knowledge of pathological processes. The dry bones of anatomy have been given fresh life by the comparative researches of Dr. F. Wood Jones, professor of anatomy at the University of Adelaide, who has made clear the phylogenetic history of many human organs. Dr. E. Mellanby, professor of pharmacology at Sheffield, is known chiefly for his exhaustive experimental researches into the aetiology of rickets; the whole science of dietetics has been profoundly influenced by his work. Dr. J. A. Murray, director of the Imperial Cancer Research Fund, worthily represents pathology in the list. For 20 years he has been engaged in initiating, organising, and consolidating the experimental study of cancer, and it is due largely to the high tradition inspired by his unobtrusive work that the laboratories of the Fund have acquired fame. We offer cordial congratulations to the recipients of a coveted honour.

TREATMENT OF GONORRHOEA BY CATAPHORESIS.

THE cataphoretic application of colloidal silver in the treatment of gonorrhœa was discussed over a year ago at the War Section of the Royal Society of Medicine,¹ when Major A. T. Frost reported on the promising results he had obtained by this method in some 107 cases. Since then a considerable amount of research has been carried out on the microscopical study of the behaviour of the gonococci and leucocytes under the electric currents—a line of research which was suggested by Sir William Leishman—and at a recent meeting of the War Section Major Frost demonstrated the outcome of this work and described in detail the treatment at present used by those who are investigating the cataphoretic method. Many disappointments have been experienced, but the system of treatment for anterior urethritis which is at present employed has achieved a high percentage of cures.

The method as described by Major Frost is as follows: The patient, on entry, is treated with daily vaccine injections, 5, 10, 15, or more millions, with a daily increase, but not to the extent of developing a negative phase. When he undergoes the cataphoretic treatment the patient is seated on an electrode, a square of copper gauze, wired

¹ THE LANCET, 1923, ii., 1134.

to the circuit, and shaped to fit the perineum very accurately, covered with lint which has been well boiled in distilled water to wash out any electrolyte; to this lint is connected the 1-inch bandage, also well boiled in distilled water, with which the penis is carefully bandaged. The urethra is washed out, first, with 0.2 per cent. lime-water, to dissolve away the mucus, then with distilled water, to remove electrolyte, and then into the bladder is injected some 200 c.cm. of chemically prepared silver colloid, made with trebly distilled (pH 5) water, and made alkaline (pH 7 or 8) with NaOH solution, 0.13 g. to the litre. A glass nozzle is adjusted to the meatus; it carries within it a platinum electrode. The urethra is filled with the silver colloid solution, but instead of an alkali, gonococcus endotoxin, the equivalent of half-a-million gonococci to the cubic centimetre is introduced. Through this system is passed a current (which must not cause pain), probably of 90 to 100 volts, and 2 milliamperes.

For the first ten minutes the lower pad is negative, and the pole in the nozzle positive. The gonococci are attracted out of the tissues along with the leucocytes, and they adhere to the positive pole, from which they may be recovered and microscopically identified later. The colloid is attracted to the negative pole, that is, into the tissues, which it permeates to a depth of 1 mm. or even 2 mm. After ten minutes the current is reversed, and for the next ten minutes the colloid is changed by the hydroxyl ions streaming out of the tissues. The change in pH and the lessened specific gravity of the solution kill the gonococci, and cause the leucocytes to swell. The destroyed gonococci and cells now try to push their way into the tissues, where, being dead, they are thought to raise immunity. This treatment is repeated daily for two or three days.

The interest of this method lies in its direct attack on the gonococcus, the cause of the trouble. It is conceivable that this method of direct attack may prove useful in other diseases, and we await with interest the publication at length of this paper in the journal of the Society, with a full account of the necessary safeguards.

HUMAN MILK IN COMMERCE.

A WELL-KNOWN student of pathology recently produced for analysis what seemed to be a singularly original dream. He had dreamed that, along with an enterprising friend, he had engaged in the manufacture of cheeses, and had put upon the market a small flat article which at once took the fancy of the cheese-eating public and sold in prodigious numbers. He and his collaborator left a life of studious penury for one of affluent ease, constantly cheered by the sight of their cheeses in every shop window. But at the height of their prosperity the pages of the daily press explained to horrified millions that the cheeselets so dear to them were made from human milk; public opinion was revolted and the makers had to fly the country. The meaning and interpretation of which may be left to the psychologists. But it is worth the notice of the telepathists that this dream was dreamed just about the time when the *Journal of the American Medical Association* was printing in Chicago a most interesting article by Dr. B. R. Hoobler, of Detroit, on the commercial production and distribution of human milk in that city, where, as THE LANCET mentioned lately, every nurse has her own bathroom. For the past ten years in connexion with the bureau of wet-nurses an organisation has existed there for collecting and distributing human milk. Carefully selected mothers supply clean milk to the bureau at a flat rate of 10 cents an ounce; in 1923, 63,722 ounces were so supplied, and mothers have earned as much as £700 in one lactating period. The milk is disposed of partly to patients who pay from 30 to 10 cents an ounce, to institutions who pay 8 cents, and to poor patients who pay nothing; the supply is normally greater than the demand, and the excess each day is distributed free of charge to

hospitals caring for sick and premature infants. The turnover is about £2000 a year, and the organisation occupies quarters in the Women's Hospital and Infants' Home, of which it is an integral part. There is, of course, no panacea for the many idiosyncrasies of babies who quarrel with their food, but this sort of provision must necessarily do much useful work in getting a certain number of infants over the rough places which they meet so often, and it is little remarkable to read at the end of Dr. Hoobler's account that electrical milking machines are to be installed.

A SUPRACLAVICULAR PROTUBERANCE IN PLETHORA.

Two years ago Prof. C. Trunczek, of Prague, published his theory of vascular hypertension, according to which all cases of this condition may be attributed to one of two primary changes, either a diminution of the vascular capacity or an increase in the quantity of blood. In the first case the contraction of the peripheral arteries causes anæmia of the skin, and hence hypertension; in the second variety, on the other hand, the increased vascular content causes distension of the vessels, especially of the capillaries and veins, which results in turgescences of the skin and numerous membranes. Prof. Trunczek now draws attention¹ to an anatomical peculiarity in this second variety which, from its constant and obvious presence, furnishes a characteristic symptom of plethora. Normally, the clavicle forms a slight prominence and the supraclavicular fossa, more marked in children and young adults, tends to diminish and gradually disappear with increasing years. Some individuals in this region show, in place of a fossa, a manifest protuberance which, in many instances, rises very markedly above the upper border of the clavicle. At the same time, the skin and visible mucous membranes are hyperæmic and turgid, the arterial pulsation hard and full, the veins and capillaries distended like the arteries, which usually appear normal in structure and feel. The area of hepatic and splenic dullness is enlarged, the number of blood corpuscles increased, and the blood pressure high. The complex of these symptoms constitutes the clinical picture of plethora, and the supraclavicular prominence is a feature of plethora. When it is small, it appears as a round or oblong mass, and when more pronounced has the form of a swelling, flat-topped and often unequal on the two sides; smooth, soft, elastic, and mobile. Percussion over the protuberance gives a dull note, and this characteristic distinguishes it from the bilateral prominences often met with in cases of pulmonary emphysema, the plethoric swelling being formed of turgid and dilated veins and capillaries which, in the supraclavicular triangle, are only feebly protected by soft tissues. The supraclavicular protuberance is of considerable importance in the diagnosis of plethora, since it is the most prominent symptom of excessive fullness of the vascular system; it has, moreover, the advantage of being easily recognisable, while other pathognomonic symptoms of this condition, although not less certain, require for their recognition much more time and clinical experience. It is also a valuable symptom for prognosis and treatment. It is a fact that in some patients who have the supraclavicular swelling the arteries are soft and the plethora not extreme, but when these same patients are seized with some acute disease, such as pneumonia or pleurisy, they are in real peril owing to the excessive quantity of blood in the pulmonary vessels and danger of acute pulmonary cedema. In such cases the excrescence, Prof. Trunczek holds, is an infallible sign which indicates the danger and points to an efficacious treatment. With the object of lessening the quantity of pulmonary blood as swiftly as possible, nothing is more efficacious than a copious bleeding, which,

¹ La Riforma Medica, Nov. 10th, 1924, vol. xi.

however, would be dangerous in patients with arterio-sclerosis, on account of the cerebral anæmia it may produce. It is therefore safer, according to Prof. Trunczek, to apply cupping glasses over the chest, which procedure, although abstracting a smaller quantity of blood in comparison with phlebotomy, has the advantage of drawing the blood in the lungs directly towards the surface, the veins and capillaries of the thoracic wall being in direct communication with the pulmonary vessels. The supraclavicular swelling may be seen to become smaller under this treatment, as it does when cachexia supervenes in such patients, in which case, on the other hand, it is of unfavourable prognosis. The supraclavicular protuberance often occurs during various chronic diseases, such as obesity, nephritis, alcoholism, and especially arterio-sclerosis, but in whatever malady it develops it constitutes a sign that the vascular system contains too much blood. A similar condition has been observed by H. Senator in splenomegalic erythrocythæmia, Vaquez disease, in which the protuberance is generally more marked on the right side. In the hypertension associated with narrowing of the smaller arteries, even when in an advanced stage, the supraclavicular prominence is not, as a rule, present. In plethora it must be considered as a phenomenon having as its object the restitution of the equilibrium the organism has lost by reason of the excess of blood in the vessels and the accumulation of it in a harmless position, Nature thus sparing regions more active and more important.

PROGRESS IN COMBATING VENEREAL DISEASE.

A JOINT deputation of the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Disease will be received by the Minister of Health on March 3rd. The object of the deputation is to urge the Minister to give effect to the recommendation of Lord Trevethin's Committee "that the law should be altered so as to permit properly qualified chemists to sell ad hoc disinfectants, provided such disinfectants are sold in a form approved and with instructions for use approved by some competent authority." Sir Auckland Geddes will head the deputation. In this connexion the Ninth Annual Report of the National Council for Combating Venereal Diseases, which covers the period June 1st, 1923, to May 31st, 1924, deserves careful reading. Opening with a warm tribute to the work of Sir Malcolm Morris, who devoted his time and abilities during the last years of his life to promoting the N.C.V.D., it is shown how for the past ten years the Council has entered into an intensive campaign in furtherance of treatment for those infected with venereal disease and has been engaged in enlightening the public on the need for those who have been exposed to the risk of infection seeking and continuing treatment until all danger is passed. Efforts have also been made to secure a broader outlook from parents and teachers towards problems of sex, that the rising generation may obtain clear and simple teaching on the facts of life, and great endeavours have been made to give practical effect to the Trevethin Report. In spite of the limited powers of local authorities to incur expense on public health propaganda progress has been made here by arranging public health campaigns in which the subject of venereal disease is dealt with as a part of a programme which includes such subjects as infant welfare and tuberculosis, and the National Council equipment may be used for this purpose on the payment of a small fee. The international aspect of the Council's work is proved by the success of the Colonial Commissions which were despatched in 1920,¹ for proposals have now been made that similar travelling bodies of experts should visit the Provincial and State Governments of India, Egypt, and certain of the Mandated territories. There are

now 18 countries represented on the Union Internationale, and the Minister of Health has appointed Colonel L. W. Harrison to attend as an observer at the meetings of the Union for the purpose of giving information on technical matters. Statistics show that venereal diseases in this country are on the decrease. The total number of new cases in England and Wales presenting themselves for treatment at the official treatment centres in 1920 amounted to 105,185, while by 1923 they had fallen to 73,613. The syphilis cases have fallen from 42,805 in 1920 to 23,927 in 1923, and the gonorrhœa from 40,284 to 30,902. While there seems to be some evidence that many who expose themselves to the risk of infection seek early advice—over 17,000 people not suffering from venereal diseases presented themselves at the clinics—it is unsatisfactory to note that there is a grave discrepancy between the number of women and men coming under medical care. In countries where a comprehensive following-up system has been found possible there is no such discrepancy, and presumably a large number of married women in this country who are suffering from gonorrhœa are unaware of their condition and are not receiving treatment. It may be noted that the fall in the syphilis figures in this country corresponds with a similar fall in other countries where facilities for treatment are provided. The Report is published at 102, Dean-street, Oxford-street, London, W. 1.

LOCAL ANÆSTHETICS.

THE use of local anæsthesia in dentistry in this country far outrivals its use in surgery, though there are signs that surgeons are becoming more alive to its advantages. In the majority of dental cases, at any rate, the operator can be assured of a satisfactory loss of sensation. There are, however, certain minor disadvantages, such as after-pain, swelling of the tissues, and toxic symptoms, which occur sufficiently often to detract somewhat from the value of this method from the patient's point of view. The toxic symptoms are of varying degree, sometimes serious but more often only unpleasant. It goes without saying that a competent knowledge of the anatomy of the fifth nerve and of the technique of injection is a qualification essential to every dentist who performs a local or, still more, a regional injection. While the chief element in local anæsthesia is the anæsthetic drug used, it is becoming widely recognised that the vehicle in which the drug is given and the presence of adrenalin, which is generally combined with the anæsthetic, are factors of great importance. Moreover, the pharmacology of the whole solution must be taken into consideration. The paper read by Mr. F. N. Doubleday before the Odontological Section of the Royal Society of Medicine on Feb. 23rd, which is reported on p. 437 of this issue of THE LANCET, is one of the most important contributions to the science of local anæsthesia which has been made in this country. It represents a large amount of original research and embodies findings of great interest. Mr. Doubleday's work was chiefly carried out on frogs and appears to cover almost the whole range of the subject. There has been much discussion on the toxicity of the various drugs employed. Experiments to determine the lethal dose of the different anæsthetics have shown that cocaine, though the most potent, is also the most toxic. The dose used in dental operations is not generally one which should be dangerous even though cocaine be used, although fatal accidents have happened and toxic symptoms of a disquieting nature have often occurred. Since it is the invariable rule to use adrenalin in order to limit the extent of anæsthesia as well as to intensify its action, it has been argued that the toxic symptoms may well be due to the adrenalin rather than to the cocaine or novocaine. Mr. Doubleday found that an anæsthetic dose of either novocaine or cocaine without adrenalin did not appear to have any effect on the action of the heart

¹ See THE LANCET, 1920, ii., 1276.

over many hours. A large number of cardiac tracings were shown which proved this point. But if adrenalin to the amount of 5 minims of a 1 in 50,000 solution was added, the effect on the heart's action was remarkable; action became slower and diminished in intensity until there was a failure of auricular contraction. Some experiments were carried out to ascertain whether it was possible to add a cardiac stimulant to the solution to counteract the depressing effect of the adrenalin. Neither caffeine nor strychnine had any effect. The addition of atropine, however, completely overcame the effect of the adrenalin, so that the action of the heart after injection was hardly affected. It is generally taught that the medium in which the anæsthetic is dissolved should be isotonic with the blood, and it is customary to dissolve the drug in Ringer's solution; but in order to ensure sterility of the solution it is desirable to boil it, and this must destroy the isotonicity. It is probable that the solution as injected is usually hypertonic. Mr. Doubleday showed by means of blood-films the crenation of the corpuscles that follows a hypertonic injection, and he suggests that such an injection may be one cause of after-pain. He recommends as a solution 50 per cent. of Ringer with an equal amount of tap-water. He finds that this solution is isotonic after boiling. This difficulty might be overcome by using ampoules of prepared solution, but there is the disadvantage that the solution would then have to be used cold; and experiments on frogs seem to suggest that a solution at body temperature causes less discomfort than a cold solution. In making a mandibular injection it is regarded as important to avoid injecting the solution into the internal pterygoid muscle, since this also is supposed to be a cause of after-pain. There would seem to be good grounds for this belief. Mr. Doubleday showed slides of muscle into which an injection had been made; the effect of the injection was to cause separation of the muscle-fibres and this might well account for the pain which sometimes follows a mandibular injection. In Mr. Doubleday's experiments the injections were made into connective tissue and not direct into the venous system. As he pointed out, in dental injections the needle is passed into connective tissue and only by accident into a vein. The absorption must be less rapid under these conditions, and these experiments therefore conform more to the actual practice of local anæsthesia in dentistry than experiments which have been made on the effects of adrenalin and other drugs by direct injection into the blood-stream. It would be unsafe to apply Mr. Doubleday's findings on a cold-blooded animal like the frog directly to such different conditions as obtain in man; yet the thoroughness with which they have been carried out, and the wide range they cover, renders his contribution highly suggestive for further research.

SECRET REMEDIES FOR FOOT-AND-MOUTH DISEASE.

THE Minister of Agriculture was asked recently in the House of Commons whether his attention had been called to Dr. John Shaw's remedy for foot-and-mouth disease which had been tried in this and other countries and proved successful; and if not, whether he would give immediate instructions to his department for an official test. Mr. E. Wood replied: "I am aware of claims made in regard to the efficacy of Dr. Shaw's remedy, and I have decided that this particular remedy shall be tested officially." We believe that the composition of the remedy in question is secret and that it has also been advocated by Dr. Shaw not only as a preventive and cure for foot-and-mouth disease in animals, but also for other diseases—e.g., influenza, for which it was originally devised. It is called by its author a "serum" and is administered parenterally. There appears to be no *a priori* reason for testing this remedy in preference to the other thousand and more proprietary medicaments which

are continually being pressed on the notice of the official veterinary service by more or less interested advocates. The alleged trials abroad of this particular "cure" have never been substantiated by reports of properly controlled experiments. It so happens, however, that an experiment has already been carried out in this country by a farmer who subjected his stock to prophylactic inoculation with Dr. Shaw's "serum," but nevertheless experienced an outbreak of foot-and-mouth disease among the same cattle eight days later. Any reasons which may exist for expending the time of the staff of the Ministry of Agriculture in testing this remedy do not appear to be supported by veterinary or other scientific evidence in favour of its claims. It seems rather that the Ministry must have yielded to the importunate pressure of ill-advised agriculturists who, dreading the disease, have been induced by high-sounding promises to turn their attention in this unprofitable direction. Now that serious scientific investigation of foot-and-mouth disease has been set on foot in this country and that there is a good prospect of the whole question of prevention being investigated from a broad and scientific point of view, it is unfortunate that delays should be introduced and recourse had to guesswork. It must be remembered that effective trial of this or similar secret remedies must inevitably hinder the serious research work now in progress. Members of the medical profession are usually well aware of the ethical disadvantages and almost invariably futile nature of secret remedies, and are therefore able to sympathise with the troubles of their veterinary brethren in this respect.

WE are happy to record a continued improvement in the condition of His Majesty the King. It is understood that no further bulletins will be issued.

WE regret to announce the death at Salcombe, Devon, at the age of 79, of Sir Thomas Edward Thorpe, Fellow and former Vice-President of the Royal Society, a past President of the Chemical Society, and famous all over the world through the Dictionary of Applied Chemistry.

FROM Ireland comes the news of the death of two leaders of the profession, Dr. George Sigerson, professor of biology in University College, Dublin, and Dr. Alfred Smith, who was professor of midwifery in the same College.

THERE will be a contested election in the representation of the Faculty of Medicine on the Senate of the University of London, and Sir G. Lenthal Cheatle, who is standing as a candidate, has circulated the reasons why he considers that there should be opposition to the sitting member, Sir Holburt Waring. Those reasons are based on Sir Holburt Waring's favourable attitude towards the recommendations in the Haldane Report. Sir Lenthal Cheatle objected to the concentration of the University on the Bloomsbury site, and to any changes in the Faculty of Medicine which might place all the medical schools, save those becoming "constituent colleges," in a disadvantageous position. Further, the circumstances in which a new degree in Pharmacy has been created are considered by Sir Lenthal Cheatle to be derogatory to the Faculty of Medicine, and in his circular he pledges himself, first, to oppose the Haldane recommendations root and branch, and, secondly, to support the authority of the Faculty of Medicine on every occasion. He is nominated by Mr. Victor Bonney, Sir Charlton Briscoe, Mr. Herbert Clogg, Sir Thomas Crisp English, Mr. Percy Legg, Dr. Willoughby Lyle, Sir Humphry Rolleston, Dr. Arthur Whitfield, and Sir Almroth Wright. The election takes place in the University of London at 5 P.M. on Tuesday next, March 3rd.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXI.—LOBAR PNEUMONIA.

In the treatment of a self-limited disease such as lobar pneumonia, the nursing and general management of the case are of greater importance than the exhibition of drugs. At present, however, the help which is afforded by drugs in the symptomatic treatment of the disease is apt to be somewhat underestimated, in part no doubt due to a healthy reaction from the days of the so-called "heroic" treatment by blistering, bleeding, tartar emetic, &c., and in part due to the search for purely specific remedies, such as anti-sera or vaccines. Treatment by specific anti-sera is effective only against infections with the pneumococcus belonging to Group No. 1, and since these constitute only some 33 per cent. of all cases, it is obvious that, in the treatment of the majority of cases, we must depend on general or symptomatic measures.

The researches published in recent years from the Rockefeller Institute have shown that virulent strains of the pneumococcus can be recovered frequently from the mouth and throat of cases convalescent from pneumonia, and from those in attendance upon or in contact with them, whereas they can be recovered only rarely from non-contacts. The possibility that pneumonia can be disseminated by carriers should therefore be kept in mind and a careful prophylaxis instituted. The patient should be isolated in a room by himself and visitors prohibited. Particular attention should be paid to the frequent cleansing and disinfection of the mouth. The throats of all contacts should be swabbed, and if pneumococci are found, appropriate disinfectants, such as liquor thymolis diluted 1 in 10, prescribed. Sputum should be expectorated into a sputum cup containing 1 in 20 carbolic acid, or into paper handkerchiefs which can be burnt. After convalescence the room should be thoroughly disinfected, and the bedding sterilised, as in the case of any other infectious disease.

The room should be thoroughly well-ventilated and kept at a moderate temperature of 60-65° F. Nursing in the open air in this country does not seem advisable, more especially in elderly or debilitated patients. The initial rigor of pneumonia has so impressed the lay mind with the idea that the disease is due to chill that most patients are made unnecessarily uncomfortable by an excess of both bed-clothes and underclothes. A light flannel jacket, opening down the front, is ample, and allows the necessary examination of the patient without discomfort or fatigue. After the diagnosis has been made the patient should be disturbed as little as possible by physical examination. The heart and front of the chest can be examined without causing any discomfort. He should be allowed to assume the position in which he is most comfortable, but, if very ill, the position should be changed from time to time to avoid congestion of the bases. Even if the temperature is not unduly high, tepid sponging twice a day, if skilfully carried out, is comforting. When the temperature exceeds 103° F., tepid or cold sponging is repeated more frequently, and where the range of temperature is still higher, and there is danger of hyperpyrexia, sponging with iced water and the application of cold compresses to the thorax and abdomen should be carried out.

At the commencement of the disease the bowels should be thoroughly evacuated by calomel, gr. ii. to iii., followed by a morning saline aperient. Throughout the course of the disease constipation must be avoided by the regular use of salines or other aperients. In many cases abdominal distension

is a distressing symptom, which is best relieved by the use of turpentine stupes, turpentine enemata, and the passage of a rectal tube. Where the distension is severe, small doses of pituitrin ($\frac{1}{2}$ c.cm. hypodermically) are useful.

The diet should consist mostly of milk and semi-fluid foods, such as arrowroot, cornflour, or the various prepared foods; fruit juices; custard; junket; soft-boiled eggs. Two or three ounces of sugar in the 24 hours is a valuable addition to the diet, and can be given as lactose in the farinaceous foods or as glucose in the fluids. In children especially good plain chocolate is a convenient method of giving glucose. Home-made lemonade, prepared from fresh lemons and sweetened with glucose, is a palatable beverage, of which the patient should be encouraged to take two or three pints in the 24 hours in order to promote an efficient action of the kidneys. For the first 48 hours fluids only—milk, lemonade, beef-tea, fruit juices—should be given.

Relief of Pain and Cough.

The relief of pain and the procuring of rest and sleep are two of the most important principles in the treatment. For the relief of the pleuritic pain, linseed poultices, renewed every two or three hours, are effective, but when skilled nursing is not available the frequent changing of the poultices may cause considerable disturbance of the patient. The weight of the poultice, too, is a disadvantage, and in children especially may add seriously to the already embarrassed breathing. Antiphlogistine is therefore preferable, since it is equally effective in alleviating the pain, it is readily applied, and it does not require to be renewed oftener than once in 24 hours. The very painful, frequent, non-productive cough of the early stage of the disease should be controlled by a sedative linctus, or a preparation such as glycoheroin, 1 drachm repeated as necessary. Many patients are allowed to become exhausted from lack of sleep, due to the frequent warnings against the use of morphia in this disease. The milder hypnotics, such as bromide, chloral hydrate, &c., may be tried, but they are generally ineffective, and opium or morphia in some form is necessary. Dover's powder in 10-grain doses is frequently successful, but if it fails, morphia, gr. $\frac{1}{4}$, combined with atropine, gr. 1/120, should be used hypodermically. In the later stages, where the toxæmia is very great and where there are signs of impending respiratory or cardiac failure, morphia is, of course, contra-indicated, but in the earlier stages lack of sleep is more dangerous than the use of opium.

Drugs have probably no effect in modifying the course of the disease, though it is customary to prescribe a simple diaphoretic mixture, such as one containing pot. cit., gr. x. to xx., liquor ammon. acetat., $\mathfrak{z}$ i. to ii., syrup aurantii, $\mathfrak{M}$ xx., aqua ad $\mathfrak{z}$ ss. A combination of pot. iod. and creosote had a considerable reputation for a time, but many patients find the creosote nauseating, and it is very liable to upset the digestion. In view of the dense consolidation of the lung, it is difficult to see how drugs belonging to the expectorant group can have any beneficial effect.

Conservation of an Efficient Circulation.

In spite of the negative findings from the pathological side, most clinicians are agreed that, in fatal cases of pneumonia, the issue is decided in the greater number by failure of the cardiovascular system, either from right-sided cardiac failure or from failure of the blood-pressure-regulating mechanism, or from both, and for these reasons the main object of treatment is to conserve and promote by every possible means an efficient circulation. As pointed out by Levy,¹ aside from structural changes, the three factors which throw an added burden on the heart are (1) the impairment of the circulation in the pneumonic lung; (2) toxæmia; (3) anoxæmia.

¹ Levy, R. L.: Archives of Internal Medicine, vol. xxxii., p. 359.

Careful watch should be kept for signs of right-sided failure—e.g., an increasing cyanosis, weakening of the second pulmonic sound, slight venous stasis in the vessels of the neck, cedema of the lung bases, or a fall in the tension of the pulse and of the blood pressure. Digitalis is the most generally useful drug, and it should be used early before the signs of circulatory failure are present. Tincture of digitalis may be added to the diaphoretic mixture, or preferably given separately in 5 to 7 minim doses three times a day from the onset of the disease, increased to 10 to 15 minims, according to the necessities of the case. In cases of known cardiac disease, the larger doses are used from the onset; where cardiac failure is severe, digitalin gr. 1/100 should be used hypodermically or intramuscularly. Strophanthin gr. 1/100 may also be used hypodermically or intravenously, but only with caution in patients already under the influence of digitalis.

Falling blood pressure is always an ominous sign, and calls for more energetic stimulation of the cardiovascular system. Numerous drugs have been recommended—strychnine hydrochloride or sulphate gr. 1/60 to 1/30, camphor gr. iii. in olive oil, or caffeine gr. v. hypodermically every four or six hours. Strychnine has rather fallen out of fashion as a "cardiac stimulant," and is perhaps more useful in threatened respiratory failure. Lately I have used adrenalin in preference to any other drug, giving it hypodermically in doses of M v. to x. of 1:1000 solution every six hours for 24 to 48 hours before the crisis. Adrenalin is not recommended as a routine in all cases, but only as an emergency in those cases which show a falling pulse tension. Pituitrin $\frac{1}{2}$ c.cm. may be used in place of or with the adrenalin.

Miscellaneous Points.

Where there are signs of cedema of the bases of the lungs, or where there is excessive sweating at the crisis, *atropine* is of very great value. It should be given hypodermically in doses of gr. 1/120 to 1/100, repeated if necessary once or twice. Atropine, like adrenalin, is an emergency remedy and should be used with caution.

The use of *alcohol* as a stimulant is still much in dispute, but the general tendency seems to be to use it less and less frequently. It seems to be beneficial in certain cases, particularly elderly and debilitated patients and in those habituated to its use, and may be prescribed in doses of 4 to 6 oz. in 24 hours. In young robust people one seldom has recourse to alcohol.

Oxygen has a considerable effect in relieving the cyanosis, but generally has little effect on the dyspnoea. Its use is indicated in those cases where early and marked cyanosis is present. In private practice it is usually given by means of a wide filter funnel, held close to the nose and mouth of the patient, or by means of an ordinary gas-bag, and the patient is allowed to breathe the oxygen for 10 or 15 minutes at a time, repeated every hour or so.

Venesection is frequently recommended but seldom practised. In the obese plethoric individual, with a full bounding pulse and marked cyanosis, the withdrawal of 15 to 20 oz. of blood at the beginning of the illness gives considerable relief to the symptoms. Later on in the disease it is indicated in any case presenting signs of right-sided cardiac failure. A mild delirium is not uncommon in many patients, preceding the crisis, but an active, noisy delirium occurring early in the illness adds greatly to the responsibilities of those in attendance on the case. Paraldehyde in doses of 2 to 4 drachms, repeated as may be necessary, should be tried. Constant observation is essential in all cases of delirium.

Specific Therapy.

Specific therapy has been successful so far only in cases infected with pneumococci belonging to Group No. 1. An anti-serum has been prepared against Group No. 2 pneumococcus, but has not been successful. The results, even against Group No. 1 infections,

are much inferior to those obtained by the use of anti-sera in diphtheria. A specimen of sputum should be sent to the laboratory in order that the group to which the infecting organism belongs may be determined. A minute dose of the serum, 0.02 c.cm. of a 1:10 dilution is injected intradermically, in order to determine the patient's sensitiveness to serum. If the patient is sensitive, or if he has already received injections of serum for some other disease, he should be desensitised by repeated small doses given at intervals of half an hour, 0.01 c.cm.; 0.1 c.cm. and 1 c.cm. hypodermically. The serum should then be diluted 1:10 with normal saline solution raised to body temperature, and injected slowly. In ordinary cases the serum should be diluted with equal parts of normal saline solution. Large doses are necessary, as much as 100 c.cm. in the first 24 hours, and 40 to 50 c.cm. on subsequent days. A dose of 30 to 40 c.cm. of serum should be injected and repeated at eight-hour intervals. Serum treatment in this as in other diseases should be commenced as soon as the diagnosis and the type of infecting organism are established. The necessity for very large doses and for the intravenous route are serious drawbacks to the routine use of serum in private practice. Vaccines, whether autogenous or stock, do not appear to have any very beneficial result except in cases of delayed resolution.

In ordinary cases where cardiac or other complications have been absent, the patient should be allowed to sit up in bed a week after the crisis, and after another week may be allowed to get up. If feasible, he should be sent to the country for two or three weeks before returning to work.

A. GREIG ANDERSON, M.D. Aberd., M.R.C.P. Lond.,
Assistant Physician, Royal Infirmary, Aberdeen.

Special Articles.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

(Continued from p. 405.)

In the three previous articles a summary has been given of the official evidence on Medical Benefit, except in so far as it relates to the work of the Regional Medical Staff of the Ministry of Health and the Certification Rules. These affect both the doctors and the Approved Societies, and a summary will be given later before the evidence given by Approved Societies is dealt with. At this stage the official evidence on financial provisions and on Scottish questions is inserted.

FINANCIAL PROVISIONS OF THE ACT.

The official account of the financial structure and resources of the Act and of the accounting arrangements (Section D of the Appendix) was supplemented by the oral evidence of Mr. E. J. Strohmenger, C.B. (App. D. 2.) The moneys, consisting of accumulations of contributions, which constitute the permanent balances in the National Health Insurance Fund, belong in the main to Approved Societies, some 98 per cent. of the insured population being members of Approved Societies. In general the summary of the evidence which has been extracted will, therefore, relate to the funds of Approved Societies, the evidence as to the small percentage appertaining to the Deposit Contributors' Fund, the Navy and Army Fund, &c., not being of general interest.

* References to the official statement which has been issued as an appendix in four sections are given thus: Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

(Q. 2133-4.) The National Health Insurance Fund acts as banker for the societies, and also acts as a general clearing house for all financial transactions involved in the scheme. The disposal of all moneys in the National Health Insurance Fund is fixed by statute, and there are no funds which are available for other purposes. (App. D. 6-9.) The receipts of the N.H.I. Fund consist of the contributions paid by employers and employed, the State grants, which consist of two-ninths of the cost of all benefits and of administration, and the interest on investments. The payments out of the fund consist of (1) the sums necessary to pay cash benefits and to pay doctors and chemists and expenses of administration, and (2) the sums issued from time to time to societies for investment.

Contributions and Reserve Values.

(Q. 2137, 2374-81.) The flat rate of weekly contributions under the Act is the rate required for the ordinary benefits in the case of a boy (or girl) of the age of 16 on entering into insurance. If there is added the contribution of the State, the value of the 10d. paid by the boy of 16 and by his employer exceeds the value of his benefits; the State contribution in respect of all insured persons is really required in order to make everybody 16.

(Q. 2154-8.) A "Reserve Value" is a paper credit in respect of every person admitted to insurance over the age of 16. These paper sums are credited in the accounts of the Approved Societies and will be gradually liquidated over a long term of years out of the margin available from the contributions and interest on investments. The amount of these paper reserve values originally created was 65 millions, and when the contributions and benefits were increased by the Act of 1920 further reserve values, estimated to amount to 48 millions, were created.

Investments.

(App. D. 17.) The balances in the National Health Insurance Fund are in the first place temporarily invested with the National Debt Commissioners. Subsequently, one-half of any sum ascertained to be available for permanent investment by an Approved Society is transferable to the N.H.I. Fund Investment Account and is placed to the credit of the society in that account. As regards the remaining half the society may take one of three courses—viz., it may request the Department: (1) to pay over the amount to the society for investment in the names of its trustees; (2) to invest the amount in specified securities in the name of the Minister (in the case of England and Wales) on behalf of the society; or (3) to transfer the amount together with the other half, to the Investment Account in the N.H.I. Fund.

(Q. 2400.) Why is it that only one moiety of the money available for permanent investment is allowed to be invested by the Approved Society. The Act has fixed a moiety?—That is roughly the share of the contributions paid by the insured person.

(Q. 2288-2291.) The total cash resources of the scheme for England, Scotland, and Wales as existing on Dec. 31st, 1923, were £107,000,000. Of this sum £88,700,000 is the immediate property of Approved Societies, made up of £38,000,000 Investment Account, £40,000,000 their own investments, £9,700,000 in their current accounts, and about £1,000,000 working balance in societies' own hands.

A Windfall.

(Q. 2189-94.) The witness explained that in the account of stamps sold there were accumulations, in excess of the sum paid over to the Approved Societies, which had gradually mounted up to 5½ millions. The greater part of this amount he described as a windfall. It is paid into a special fund called the Central Fund, and under the Insurance (Cost of Medical Benefit) Act, 1924, there is a special charge on that fund for certain liabilities in respect of the cost of medical benefit. Part of

the excess cost of medical benefit in the years 1924, 1925, and 1926 will be charged to that fund. At the end of 1926, when all the charges on the fund have been met, it will stand at £1,500,000 with, in addition, interest from the end of 1923, and is certainly adequate to meet its liabilities (that is, in the way of helping societies having deficiencies).

Q. If this special liability for medical benefit had not arisen and been thrown on the Central Fund, a problem as to the amount of that fund would have arisen later on, with which, I suppose, Parliament would have had to deal?—That is so. This large sum of money is wholly a windfall in any case. Q. In your view, have Approved Societies any proper claim upon it?—Practically none whatever. Q. It is absolutely a windfall?—It is absolutely a windfall.

An Impression of Considerable Complication.

(Q. 2129, 2351.) The Chairman at the outset had stated that the financial arrangements appeared to be highly technical and complicated. As to this, Mr. Strohmenger said that some of the arrangements were made in the interests of sound financial administration, but the whole scheme was really the scheme which Parliament had itself laid down.

(Q. 2360.) Asked whether the societies understood the essential features of the financial arrangements, the witness said:—

I think they know all things that they need know in the interests of their members. I should not like to say that every society really understands the whole of the financial structure of National Health Insurance. . . . The officials of the large societies of course have understood it perfectly, but I do not suppose the great bulk of Approved Society officials have a very intimate knowledge of all these mysteries, and I do not think they need have. The ordinary working Approved Society secretary who looks after his insured people and protects his funds knows, I think, quite as much as he need know. (Q. 2361.) And no great degree of simplification in the central finance of the scheme could be said to be necessary for the proper and intelligent administration of benefits by the agencies concerned?—I say that quite clearly.

(Q. 2437-8.) To those to whom ledgers are profound mysteries, there is an interesting piece of evidence with regard to the ledger work of the Approved Societies. The officials, especially of small societies, are in effect keeping a ledger without really knowing it.

We devised a scheme under which a book was given to them, arranged according to subject in columns. There was a specific instruction on each advice as to which column each entry should go into. The book really is a ledger; but instead of having a separate opening for each account, it has got columns in which the entries go. It helps the society, which has simply to look at its advices saying that a certain item should be posted in column 20, line 10, for instance. At the end of the year they simply add up the total of their entries and thus get their ledger balances.

This book gives all the material to enable a society to make up its benefit fund and to get the auditor's certificate.

The Cost of Medical Benefit.

(App. C. 142.) The cost of medical benefit has varied from time to time with the agreements entered into with the doctors' representatives with regard to the amount of the capitation fee and the sums to be allowed for mileage and with the arrangements in force in regard to the supply of drugs. The provisions of the Act at present in force (the National Health Insurance Cost of Medical Benefit Act, 1924) fix the charge for medical benefit at 11s. 10d. per insured person. The total amount required in addition to the sum of 9s. 6d. provided by the Act of 1920 is 2s. 4½d., and this is provided as follows:—

	s.	d.
(1) Out of the funds of Approved Societies, &c. . .	0	2
(2) Out of moneys in the Central Fund (as explained above) derived from the unclaimed balance of sums received from sale of National Health Insurance stamps	1	8½
(3) Out of interest earned on the proportion of insurance funds retained in the National Health Insurance Fund (Investment) Account beyond the prescribed rate credited on sums standing in that account	0	6
	2	4½

It would appear (Q. 1435-7) that this provision of 2s. 4½d. is a temporary provision, and that for the cost of medical benefit in the future in the absence of fresh legislation 9s. 6d. only will be available at the end of 1926. With regard to these provisions, Mr. Strohmenger said:—

(Q. 2238.) These financial provisions as regards medical benefit are, so far as the Ministry is concerned, extremely unsatisfactory. They constitute a serious defect in the general financial arrangements. Here you have what is really a limited provision for the payment of medical benefit and an unlimited liability. It is true that the payment to the doctors is fixed for a period of years from time to time, but there is always the risk that the time may come to review the bargain with the doctors, and to have a further liability for which you have no provision. . . . For the years 1924, 1925, and 1926, the Department made what they considered to be a very full estimate of the cost of drugs, but owing to the epidemic this spring the cost exceeded that estimate, and although I hope that, during the three years for which the Act of 1924 will run, the cost will be within the provision, at the same time it may not be, and it will be an acute embarrassment to the Department if it is not.

EVIDENCE OF THE SCOTTISH BOARD OF HEALTH.

A careful reading of the evidence given by Sir James Leishman, the chairman of the insurance side of the Scottish Board of Health, and the other official Scottish witnesses, fails to reveal any peculiarly Scottish problems which would appear to necessitate a separate Scottish administration. The contributions and benefits are the same throughout Great Britain, and Approved Societies operate in both countries. (Q. 1544.) Generally there is constant communication by letter, by telephone, by wire even, with the English Ministry; practically all documents are exchanged between the two departments; and there is a considerable measure of coöperation through the operations of the Joint Committee.

(Q. 1556.) The question whether a good deal of machinery was not thus required for the purposes of coördination, and also whether a certain amount of difficulty did not result from movements of the population, especially with regard to statistics, accounts, and valuation, Sir James Leishman said:—

Yes, there is some, but it is part of the price you have to pay for separate administration, and in my judgment the price is fully justified.

(Q. 1573.) Apart from the question of national susceptibility, do you think on the grounds of efficiency alone there is a case for separate administration in Scotland?—I think so, but I may be prejudiced.

Separate Valuation.

The witness was asked why Scotland insisted on having a separate valuation for the Scottish members of societies, and he replied that it was an indication of what might be called the "Home Rule" position.

(Q. 1894.) Has anything been gained in these international societies by having a dual system of valuation?—It is very difficult to answer that question. What we do know is that, putting the objection to uniformity on the highest plane, Scotland, on the whole, stands fairly well, and that, at all events, we have not lost anything while we have gained a certain element in our own self-respect.

The Friendly Society Movement.

(Q. 1764.) Before the days of the Insurance Act the Friendly Society movement, especially in the purely country districts, had not got such a firm grip in Scotland as it had in England. This appears to account in part for the fact that there are relatively not so many small societies in Scotland administering the Act as separate units. Although, as stated, not many problems peculiarly Scottish are dealt with in the evidence, the views of Sir James Leishman were ascertained upon various matters, of common interest on both sides of the Border, from which we make a selection.

Malingering.—(Q. 1617.) Are you satisfied now that malingering or over-generous certification is not a substantial financial danger?—It is a serious part of the

administration, but, as far as I can see, there is not a substantial financial danger.

Delay in Paying Benefits.—(Q. 1619.) While some societies are probably not so good as others, we could hardly say, viewing the position as a whole, and having regard to the fact that societies are spread all over the country, and to the fact that members are often in inaccessible places, that there could be any serious charge made of undue delay in paying benefits.

Insurance of Married Women.

(Q. 1663-1729.) Sir James Leishman was questioned at great length with regard to his opinion that married women were not an insurable proposition. He expressed himself as in favour, on the grounds of simplicity, of the view that a woman on marriage should be given some sort of surrender value. Sir Alfred Watson pointed out that a similar proposal when the Bill of 1918 was before Parliament was stoutly opposed by the representatives of Women's Societies.

(Q. 1679.) There was substituted for it the present arrangement under which a woman gets something equivalent to that surrender value in the shape of maternity benefit and a small weekly allowance for a short period of sickness?—Yes, and also medical benefit.

(Q. 1702.) Is it really the considered view of Approved Societies responsible for administering the insurance scheme that rather than have the trouble . . . of administering these benefits they would offer the woman a bribe to get out?—I would not put it in that way, not so bluntly as that. So far as I know the mind of Approved Societies—and I would rather this question was pressed home with them— . . . they would prefer that.

Sir James Leishman said that he was all for simplicity. A series of further questions, however, led to the following:—

(Q. 1729.) If you take an able-bodied young man, if he is at home you assume something is wrong, but in the case of a married woman you would not know whether it was anything more than spring-cleaning. Does it come to anything more than those two propositions?—I think you have stated the case very well, if I may say so.

Maternity Benefit in Scotland.

(Q. 1965.) Maternity benefit in Scotland has been highly popular. Positive evidence is abundant that it has greatly helped mother and child, and there has been very little misapplication of this benefit. Complaints, however, have been received that in many cases too much of the money has gone to the doctor or midwife, but, even so, the mother and child have benefited by the skill and care thus obtained.

Medical Benefit.

Medical benefit has been found to work well, even under the severe difficulties and the restricted service made necessary by the war, and very little reliable evidence has emerged of neglect of duty on the part of insurance practitioners, or of any real ground for loose general charges of inefficiency. Dissatisfaction with a limited service and agitation for an extended and complete medical and institutional service must not be fastened on as a condemnation of the working of the Insurance scheme, but rather as an indication that it has resulted in increased appreciation of the importance of a further great development of medical services in the interests of national welfare.

Early Diagnosis.

An American critic has alleged that insurance doctors are mainly occupied in dealing with trivial ailments. In so far as that is the case it is testimony to the worth of the present scheme. The facilities for treatment which the Act presents to the insured have resulted in the insurance practitioner seeing disease in its earliest and most curable stages, when there is frequent opportunity to prevent the onset of disabling or fatal illness.

Need for Specialist Advice.

The witness quoted from the Fifth Annual Report of the Scottish Board of Health, 1923, as follows:—

There is a great diversity in the range of treatment given to their insurance patients by practitioners. The work done

by many practitioners is of the very highest quality, sometimes comparing not unfavourably with that of specialists attached to hospitals. . . . There is an urgent need for increased hospital accommodation for the insured. The fullest advantage is not always taken by the practitioners of the availability of specialist advice at these institutions.

Numbers of Doctors on the Panel.

(Q. 1972.) Out of 2175 general practitioners in Scotland 1790 are panel doctors. In the county of Fife all the general practitioners are on the panel. In Glasgow† 401 out of 670 are on the panel. In Dundee Burgh the proportion is 95 per cent. In rural areas, it may be assumed that most of the doctors are on the panel, and, indeed, in a single practice area it is almost inevitable that the doctor should go on the panel. In Edinburgh the figures are 160 doctors out of about 230 in general practice. Edinburgh, said the witness, was the place where the reaction in connexion with the agitation was felt most keenly in the medical profession owing to the number of consultants who were there.

Vaccination.

(Q. 1976.) The question of preventive treatment had been the subject of an interesting decision in Scotland by referees, who had come to the conclusion that treatment should cover—

all treatment of every kind which a person is entitled to receive from any general practitioner attending him in the ordinary way; in ordinary general practice prophylactic treatment for the prevention of sickness is given, and the only change effected by the Act is that the practitioner, instead of being recompensed by fees, is recompensed by the capitation grant.

The referees, having regard to the rapid advance in medical science, added a rider that the panel doctor is not bound to undertake prophylactic treatment of any kind which has not become a matter of ordinary treatment by competent general practitioners; with regard to the particular case submitted to them, they had no hesitation in holding that any general practitioner was able to revaccinate against small-pox.

Sizes of Doctors' Lists in Scotland.

(Q. 2023.) In counties 66 per cent., and in burghs 36 per cent. of the panel doctors have less than 500 insured persons each on their lists; 18.5 per cent. in counties and 16.4 per cent. in burghs have from 500 to 1000 insured persons; and 13.8 in counties and 34.2 per cent. in burghs have from 1000 to 2000 insured persons. Those with over 2000 number 1.8 per cent. in counties and 13.4 per cent. in burghs.

Cost of Drugs.

(Q. 2024-2062.) The Scottish chemists are paid at higher rates than those paid in England, but the total expenditure on drugs is about 3d. per insured person less. This was explained as being due to differences in the prescribing habits of the doctors in the two countries. Mixtures are renewed in England 5 times to 4 in Scotland; powders 6 to 4 and pills nearly 7 to 4. The dosages are different, and it does not necessarily seem to imply that more medicine is consumed in England. (Q. 2038.) The extra cost in England is explained by the fact that each renewal carries a separate dispensing fee and separate payment for the chemist's establishment charges.

(App. II. C. 19.) The chemists in Scotland have proved more difficult in regard to terms of remuneration because, unlike the English chemists, they had not so much new business under the Insurance Act. Generally speaking, in Scotland, before the Insurance Act, the doctor had dispensed his own medicines only in country districts in which there was no chemist. In England, on the other hand, dispensing by doctors had been widely prevalent and in certain districts it was the almost universal rule. The

Insurance Act, by prohibiting doctors from dispensing medicines for insured persons, except in special circumstances, thus diverted into the hands of English chemists an increased volume of trade without conferring upon Scottish chemists an equal or corresponding advantage.

Medical Service in the Highlands.

(Q. 2119.) It is claimed that there exists in the Highlands and Islands of Scotland a combination of difficulties not to be found in any other part of the country. By means of a special Exchequer Grant—the Board have been able to make considerable improvements in the medical service, not merely in supplying surgeons and specialists, but also in raising the status of the ordinary practitioner, for example, by providing him with a living wage and helping him with a motor-car to reach his patients. The total of the grant is about £42,000 a year, but . . . that covers payments for services rendered to other classes in the Highlands besides insured persons.

Extra Payments to Medical Men in the Lowlands.

(App. II. C. 25-34.) An Exchequer Grant of £65,000 is available for the Lowlands of Scotland for mileage and also to include special grants for necessitous districts. These special grants are paid under a scheme which provides funds for maintenance of doctors in isolated areas, for the maintenance of a motor-car, for dispensary provision, removal of patients to hospital and even, in a limited number of cases, for expenses incurred by the doctor in taking leave for the purpose of a short course of post-graduate study.

REX v. BATEMAN.

ALL our readers know the successful issue of Dr. Bateman's appeal against his conviction last December, which resulted in the quashing of the sentence and the immediate release of the wrongfully convicted man. Most of us also know that these devastating occurrences in the life of a practising doctor bring with them both a train of heavy expenses and a temporary loss in professional earnings. Through representations made to us it has been found that the advocacy, from the first extended to Dr. Bateman's case in these columns, has met with the approval of the medical profession at large, and we may here say that the attitude of THE LANCET in the matter was entirely dictated by great professional motives. In our opinion from the first—and it was strongly supported by good authorities—Dr. Bateman's conviction was an example of the neglect in a court of law to give value to clinical evidence; and in a court of law, when malpraxis is in question, clinical evidence must always receive the greatest respect if injustice is not to be done. Thus juries have the right to expect that their attention will be directed, and directed prominently, to the places where clinical evidence might be expected to influence their opinion. This was not done in the case of Dr. Bateman, and the result of that case must lead to better things.

It has been felt that material assistance ought to be offered to Dr. Bateman in the present circumstances, when he has to meet the legal expenses of the appeal and to make good the deficits in his professional income. With that view we shall be happy to announce in these columns any subscriptions that may be received towards a "Bateman Fund," designed to defray the expenses which he has incurred and to assist him in temporary but very real need.

Remittances should be forwarded to the Manager of THE LANCET, 423, Strand, W.C.2, and made payable to the "Bateman Fund Account."

EPSOM COLLEGE WAR MEMORIAL.

IN 1895 the late Sir Arthur Blomfield presented his designs for the rebuilding of the old chapel at Epsom College, but because of lack of funds and other reasons, it was possible to build part only of the new chapel then planned. A new chancel was accordingly built and completed by the end of 1895. For 30 years the boys have used their chapel with its new chancel and old nave. The completion of the original plans has been eagerly awaited amongst all Epsomians past and present, and the Council, actively supported by the Old Epsomian Club, decided that no more fitting war memorial to the

Lambeth Parish Church (where the school has its mission), the vicars of Christ Church and St. Barnabas, Epsom, and the two school chaplains. After the Bishop's procession had entered the chapel, wreaths were placed beneath the war memorial tablet by the head prefect, the second master, and the president of the Old Epsomian Club, and then the headmaster read the names of the 140 past students and masters, of whom the new nave stands a memorial to all who follow them. The Bishop's address—"The leaves of the tree are for the healing of the nations"—while reviewing the fundamental principles for which this and all war memorials stand, came chiefly as a message to the boys of the College, emphasising that it was for them to continue the work

The New Chapel at Epsom.

old boys who fell in the late war could be desired than the completion of the chapel. After six years of careful planning the new nave has been added to the chancel. Mr. Arthur Blomfield has been responsible for adapting and carrying out his father's original designs; the work has cost £11,500, of which £2000 remains to be collected. The chapel is built of red brick with Bath stone windows and dressings, and has a seating capacity of 650. The choir are placed in the chancel facing inwards, while the seating of the congregation differs from that in the old chapel, in that chairs are used instead of pews and these all now face the east. In addition there is a gallery at the west end. The whole of the heating and lighting systems are new, while the organ has been re-erected in a new organ chamber on the south side of the nave.

On Saturday, Feb. 21st, in the presence of a large gathering of parents, relatives, and old Epsomians, the new nave was consecrated by the Bishop of Winchester "in memory of those from Epsom College who gave their lives in the Great War in the cause of Righteousness, Liberty, and Peace." The Bishop was attended by two past headmasters, Rev. T. N. H. Smith Pearse and the Rev. W. J. Barton, by two past chaplains to the College, Rev. J. M. Swift and Rev. J. A. Davies, M.C., and by Bishop Hook, the rural dean and vicar of Epsom the rector and curates of

begun with such sacrifice by their brother Epsomians before them, that is, to work for the betterment of the world and the advent of universal peace. The service concluded with the "Te Deum," the "Last Post," and the National Anthem.

Among the large gathering present were Lord Dawson of Penn, Sir Ernest Goodhart, many members of the Council, and many old Epsomians, including Dr. Arthur Napper, who entered the school in 1855, the year of its opening. To the great regret of all, Lord Rosebery, the President of Epsom College, and Sir Henry Morris, Bart., were both unable to attend through ill-health.

It may be recalled that Epsom College has now entered upon its seventieth year. It is difficult to realise that its foundation pensionerships and scholarships, its present position, and the wonderful educational facilities it offers, could possibly be unknown to any medical man or woman, but judging by the unequal support accorded to it by the profession in general this must be so. During the last few years the numbers at the school have rapidly increased, and to-day there are 331 boys, and not one more can be fitted in anywhere; there is a waiting-list of over 400 names. As recently as last December¹ we supported the appeal made by Dr. Raymond Crawford,

¹ THE LANCET, 1924, ii., 1293.

chairman of the Council, in unqualified terms and nothing further need be said now, save that the visit to Epsom for last Saturday's ceremony proved that while its medical foundation remains the very essence of its being, the College is becoming generally recognised as a public school of high standing in the country.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Tests for Motor and Tram Drivers.

THE excellent motor-bus and tram service provided by the S.T.C.R.P. (Société des Transports en Commun de la Région Parisienne) could hardly be improved, but the directors of this concern never rest on their laurels, and are always seeking to add to the efficiency of their service. The latest innovation is the provision of a psycho-technic laboratory which was formally opened last month, and which is intended as a testing-house of the human machinery employed on the motor-buses and trams. The tests conducted at this laboratory resemble in certain respects those already in general use for prospective aviators; the reaction of would-be drivers to a variety of stimuli is studied under artificial conditions made to resemble as closely as possible those under which drivers will find themselves in normal circumstances. The tests are to be applied also to drivers who have had some mishap, and whose capacity to continue at work is questioned. In addition to purely dynamic tests—i.e., investigations of the muscular power and the fatigue response of the persons examined—a number of psycho-motor tests have been devised. The prospective driver finds himself seated on a motor-bus surrounded by handles and levers and confronted by a cinema film portraying as many vehicles and pedestrians as can possibly crowd together at one time on to the road. He is further confronted by red and green lights, noises of all descriptions, and his reactions to one and all of these stimuli are faithfully and mercilessly recorded—whether he presses the right brake, and, if he is a tram driver, rings his bell at the right moment, and does other appropriate things—and thus his capacity to thread the congested streets of Paris is judged. It is proposed that every driver shall undergo the tests of this laboratory at intervals of five years up to the age of 50, by which time he will, no doubt, be ripe for a less nerve-racking vocation. Considering that the company concerned possesses 1500 motor-buses and 2506 trams it is clear that this new psycho-technic laboratory will not be idle. In France it is hoped that a service of a similar nature will soon be provided for all motor drivers, amateur as well as professional, and that a means will thus be forthcoming for the elimination of the unfit driver.

Poison Gas and Tuberculosis.

At a conference on the respiratory sequelæ of poisoning by warfare gases, held recently at Val-de-Grâce, Prof. E. Sergent, of Paris, stated that poisoning by gas, in itself, was not sufficient to cause tuberculosis—a statement which was based on clinical observations, statistics, and experimental evidence. When an aggravation or a sudden recrudescence of tubercle is observed following poisoning by warfare gas, one must assume that there has been a reinfection of the injured lung by active and latent tuberculosis. When a late pulmonary infection appears in a patient who has been previously gassed, this cannot be laid directly to the account of the gas, but other general factors must be taken into account, apart from the gas, such as accidental reinfection or recrudescence through lowered resistance in the patient.

Anti-microbic Properties of River- and Sea-water.

A most interesting communication, from the hygienic point of view, was read on this subject to

the Academy of Medicine by Dr. Arloing, professor of experimental and comparative medicine and of bacteriology at Lyons. From a study of the waters of the Rhône, the Saône, the Isère, the Brac, the Romanche, the estuary of the Seine, and the roadstead and harbour of Le Havre, he found that these waters had remarkable bactericidal properties with respect to certain organisms of the intestinal group. Dr. Arloing attributes these properties to a bacteriophagic and bacteriolytic action of the water, varying with its regional source. Thus the Rhône and the Isère have a marked antipathy towards the typhoid organisms, the Isère and other streams in the neighbourhood of Grenoble, including water from melted snow, having a particularly destructive action on paratyphoid A, while the waters at Le Havre are inimical to the *B. dysenteriae*. The bacteriolytic effect on the *B. coli* is the most general, and this is found particularly in slow-flowing, impure water (Saône, Seine, and harbour of Le Havre). The anti-microbic action is usually more marked below than above an important locality. This bacteriolytic property, from its biological character, seems to be bacteriological rather than physico-chemical.

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

Transplantation of Eyes.

SOME years ago a young Hungarian scientist, Dr. Koppányi, created a stir by his claim to have transplanted eyes in vertebrate animals with such success that a certain amount of visual power was regained through the transplanted organ. Koppányi demonstrated the results of his experiments at the Ophthalmological Congress held in Vienna in 1921, but the Congress was not prepared to regard his claims as proven. Further experiments along Koppányi's lines were, however, sanctioned by the Congress, and one of the workers who undertook research in this field was a Transylvanian ophthalmologist, Dr. Nicholas Blatt. Dr. Blatt pursued his practical investigations for over two years, during which time he experimented upon over 600 animals, 400 fresh water fishes, 200 rabbits, and several chickens. In all cases the animals were narcotised before the operation. The most that can be said for the experiments is that anatomical healing took place in 26 cases among the 400 fishes, in 2 cases among the 200 rabbits, and in no case among the chicken experiments. He made some interesting observations on such phenomena as colour change in fishes when one eye had been transplanted, that is, for all practical purposes, in fishes blinded in one eye; but out of the sum total of the attempts made to re-create sight nothing of value to afflicted human beings emerged. A rather pathetic sidelight on his work is the fact that he had to hide himself away in a small and specially erected laboratory because, when the nature of his experiments was voiced abroad, hundreds of blind people flocked to him in the hope of receiving "new lamps for old."

Anatomical Cadavera in the Rumanian Universities.

The starting-point of the anti-Semitic feeling which has run high in the Rumanian Universities during the past two years, and has led to several very regrettable incidents, may be traced to the demand of the Christian medical students that Jewish medical students should be excluded from the classes of practical anatomy, except in so far as their dissections were limited to Jewish cadavera. This demand was rejected by the professors, but the attitude of the Christian students was so firm that, in order to ensure the peaceful continuance of regular studies, a compromise had to be made, in conjunction with the Minister of Public

Instruction, whereby it was decided that in future Jewish students might carry out dissecting work only if Jewish cadavera were available. When none were available the Jewish students must not themselves dissect, but they might watch the procedure. This regulation brought about a truce, but it did not put a stop to anti-Semitic demonstrations, which, indeed, have been so frequent that military patrols were stationed outside lecture-rooms to ensure a measure of peace among the students. The Minister of Public Instruction, Mr. Anghelescu, who considers the exclusion of Jewish students from the practical anatomy rooms to be unfair, recently held a conference to discuss the whole question of Jewish cadavera. As a result of the conference, the Minister of Public Sanitation has issued an order to all hospitals demanding that the bodies of all patients who die in hospital, unless they are claimed by relatives of a definite degree of consanguinity, must be placed at the disposal of the anatomical institutes without regard as to the nationality or creed of the deceased. This order also applies to provincial hospitals, and includes the conveyance of cadavera from such hospitals to university centres.

Epidemic of Hiccough in Transylvania.

For the past few weeks an epidemic of hiccough has been prevalent in Transylvania, and cases are reported from all the towns of the country. The cases are mild for the most part, and the onset is marked by slight fever. The symptom of hiccough shows itself on the third or fourth day, and lasts generally two or three days. In treatment, aspirin in fairly large doses has been the main stand-by, specific therapeutic measures having proved inefficacious. In some old subjects the fits of hiccough are very difficult to stop, but aspirin usually brings relief. No fatal case has as yet been recorded.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Hardships in the Medical Profession.

THE economic conditions prevailing in our country are weighing heavily on the medical profession. Not only is the standard of living quite different from that to which we were accustomed a dozen years ago (it is at least 50 per cent. lower as regards culture and outward appearances), but also the level of fees has dropped alarmingly. Eighty per cent. of the population belong to one or other of the different sickness insurance clubs, which cuts out many opportunities of private practice. The average income of a busy general practitioner in our city is about £25 a month—and that is a bare living wage. Only about 12 per cent. obtain £30-£40 a month, and not more than 2 per cent. have more than £80. Specialists as a rule have slightly higher incomes, but few earn more than £50, whilst £100 represents a flourishing practice. Under such circumstances—the cost of living here being about the same as in England—a large number of doctors have given up their profession and have become agents for surgical instrument factories, or for chemists or pharmaceutical concerns; many have taken up a purely commercial career.

Atypical Measles.

In a memorandum addressed to the practitioners in Vienna Dr. Friedjung draws attention to the fact that the type of measles occurring in the outbreak which has been present in our city for the past month is quite different from the disease described in textbooks. On the whole, the decursus has been very mild, with few complications from the ears or the lungs. The prodromal symptoms are insignificant; now and then one notices a little redness or soreness of the throat, some cough, but no Koplik's spots. Then a violent and intractable cough develops, and the rash appears suddenly with high fever. At this stage,

and not before, Koplik's spots appear. The disease then runs its regular rapid course, and the patients are soon well again. As there is concurrently in the city a fairly extensive epidemic of mild influenza, with similar bronchitic manifestations, one must be on the look-out. Many schools had to be closed temporarily on account of these conditions amongst the children.

The Water-Supply of Vienna.

The present unparalleled scarcity of snow and rain in the Austrian Alpine regions has caused a rapid diminution of the water-supply of the capital, which derives its water from two different districts of the Alps. The old waterworks, opened in 1885-87, comprise seven "eternal" springs at the foot of the Rax-Alp and the Schneeberg, two mountains about 60 miles to the south of Vienna. From this source Vienna used to obtain excellent water for about 1½ millions of people. The increase of the population necessitated the acquisition of new water sources. In 1910 the second waterworks were completed, embracing 22 springs, which derive their water from a distance of 120 miles to the south-west, and the combined supply was sufficient for about 2,000,000 inhabitants, giving each about 135 litres (280 pints) daily of pure water of medium hardness. But of late the average yield of the wells and springs has diminished, and the amount of water required daily per inhabitant has gone up. Plans are now being made to get a water-supply by means of artesian or other wells in the vicinity of the capital. Naturally special care will be paid to the quality of water to be added to the present supply. Already many physicians have noted an increase of goitre amongst the population. The general public believes that this is due to the Alpine water, as it comes from districts where goitre is endemic. And the coincidence of the use of the second waterworks and the increase in the incidence of goitre, especially amongst the females, is striking. When the present dry winter cut down the available daily quantity of water to about 110 litres and less per head, it served as a warning that the city could not rely on the Alpine springs alone. In keeping with modern ideas of hygiene and cleanliness, a daily average supply of 200 litres per head will be aimed at.

Final Settlement of the Conflict between Prof. Meller and the Hospital Board.

As I mentioned some time ago in a letter, a conflict had arisen between Prof. Meller, the chief of the ophthalmologic clinic and the board of the hospital and the Ministry of Health, owing to certain alleged grave obstacles placed in the way of scientific work. Public sentiment was definitely on the side of the professor, and he threatened to resign his chair and discontinue his lectures in the University. After some heated controversy an understanding was arrived at whereby the professor agreed to continue his teaching. The hospital board will no longer interfere with the administrative work of the clinic, and will not let monetary views interfere with the receiving of patients wanted for instruction or for other reasons by the teaching staff of the clinics.

BERLIN: INTERNATIONAL POST-GRADUATE COURSES IN MEDICINE.—A series of post-graduate courses at various hospitals will be held in Berlin in the spring, in conjunction with the Berlin Medical Faculty. The series will include the following: (1) Practical Course on the Diagnosis and Treatment of Syphilis, from March 2nd to 7th; (2) Practical Course in Diseases of the Digestive System and of Metabolism, from March 9th to 14th; (3) eight evening lectures on Important Points in General Medicine, during March; (4) Supplementary Course on Special Subjects in all Branches of Medicine, two sections (a) from March 2nd to 28th, and (b) March 16th to 28th; (5) Important Chapters in Social Medicine, from March 30th to April 5th; and (6) Special Course in Ear, Nose, and Throat, from April 20th to May 9th. Information as to lodgings, &c., and the full syllabus may be obtained on application to the offices of the International Post-Graduate Course, Luisenplatz 2-4, Berlin, N.W. 6.

Obituary.

THE RT. HON. SIR CLIFFORD ALLBUTT,
P.C., K.C.B., F.R.S.,

REGIUS PROFESSOR OF PHYSIC, UNIVERSITY OF CAMBRIDGE.

THE whole of the medical profession will unite with us in regretting the death at the advanced age of 88 of Prof. Clifford Allbutt. He was the acknowledged leader of the profession in this country and had attained to this position by outstanding clinical experience, by an unrivalled knowledge of the literary side of our science, and by a wonderful ability to deal with men and things, as shown by his success in the tenure of high office, in academic teaching, and in practical politics. He died suddenly at 1 A.M., after 10 minutes' acute dyspnoea, on Sunday last in full possession of all his faculties and discharging with promptitude until the end his official duties at the University. Only three days before his death we received from him a communication, which will be found in our correspondence columns, showing how keenly alert he was to the salient points in any discussion in contemporary medical journals, and also displaying in its phraseology his unvarying intention not to overstate a case. He offers no explanation of the phenomena, but reports an empirical result, knowing that on the sum of such results explanation may follow. Throughout 65 years of professional work he always maintained a similar logical outlook.

Thomas Clifford Allbutt was the son of a Suffolk clergyman and was born at Dewsbury in Yorkshire and educated at St. Peter's School, York. From school he entered Gonville and Caius College in the year 1857 as a scholar and graduated in the first class of the Natural Science Tripos. From Cambridge he went to St. George's Hospital and while there graduated in medicine at Cambridge and held the usual resident hospital appointments. Shortly afterwards he took up his residence at Leeds, where his professional career was from the first an unqualified success. For while he rapidly made a name for himself in scientific circles, he also obtained a huge consulting practice, but managed to discharge at the same time, and zealously, his duties as physician to the Leeds General Infirmary, the Leeds Hospital for Women and Children, and the Leeds Fever Hospital. His reputation and his influence alike spread far into the north of England, and the seniors among us can still remember when his opinion was constantly quoted over a wide range of work as coming from "Allbutt of Leeds." As early as 1868 his share in the improvement of clinical thermometry was recognised as fundamental, and he has himself recorded what that share was. The first clinical thermometers were those of Casella, constructed for the well-known Prof. Aitken of Netley. But these were too cumbersome for general practice, and for this reason the thermometer long remained a stranger to the busy practitioner. Allbutt set to work with Messrs. Harvey and Reynolds to manufacture an accurate thermometer of a new form to be carried in a portable case, and in a paper by the late Prof. Sims Woodhead and Mr. Varrier-Jones, published in our columns about eight years ago, Allbutt's own account of his share in perfecting the device is given. The value of the new instrument in medical investigations was not recognised quickly, despite the advocacy of Aitken and Pridgin Teale, Allbutt's colleague at Leeds, but when the enormous aid to diagnosis furnished by the self-registering instrument was once perceived there was hardly a practitioner in the country who did not wonder how he had been able to dispense with it.

A second prime contribution to the technical side of scientific medicine was also made by Allbutt at an early stage of his career, for although no particular ophthalmoscope bears his name, no one man contributed so largely to the recognition of the value of the ophthalmoscope in the earliest days of its inven-

tion by Helmholtz. Fifty years ago, when the ophthalmoscope was a comparatively new instrument, many who employed it were too sanguine of the gains to accrue from the recently acquired power to see nerves and blood-vessels in such immediate relation with the brain. They saw that the instrument should pave the way to an improved diagnosis of cerebral affections, and the discovery of the forms of retinitis that depend upon renal or other remote disorder was hailed as sure to lead to advances not only in diagnosis, but also in pathology and therapeutics. But as time went on, these expectations became less confidently expressed, for it was apparent that the new page opened to clinical observation was not of the kind which he who runs may read. Persons unskilled in the use of the instrument, and unable to interpret the appearances that it revealed, not infrequently made and published serious blunders; they afterwards neglected the help they had misused. In the meantime a few patient workers toiled steadily on, collecting data, comparing evidence, and eliminating sources of error. Among these workers Clifford Allbutt was one of the most prominent, and at the proceedings of various medical societies and in our columns and in those of other professional journals he explained methodically the use of the ophthalmoscope, defining its range and annotating the phenomena made apparent by its use. In 1871 he brought all this work together into a connected volume which was the only existing general treatise upon its subject at the time. The book, which dealt with the use of the ophthalmoscope in diseases of the nervous system and of the kidneys in particular, but which took note of the employment of the new system in many general disorders, began with an emphatic and personal testimony to the value of the direct image in the recognition of early and slight changes, explaining the common sources of error in interpretation. An orderly account was then given of the variations from health of the optic nerve and the retina, while the relations between these variations and intracranial and other general disorders was closely discussed. The work was recognised from the first as full of sound reasoning founded upon careful observation, never carrying conclusions further than the facts would warrant, but bringing together all the facts as far as they could be ascertained to bear upon the questions at issue. The book was reviewed in THE LANCET just 53 years ago, and how much it was needed is indicated by the last words written about it, which were: "It will convince the most sceptical that the ophthalmoscope is an instrument no longer to be neglected as a means of diagnosis in general medicine." In the same year he read before the Royal Society a paper entitled the Effect of Exercise upon the Bodily Temperature, to which Society he was elected in 1880 in recognition of his original and scientific services to clinical medicine. In 1883 he was elected F.R.C.P., having in the meantime taken his M.D. at Cambridge, and in the following year he delivered the Goulstonian Lectures of the College, taking as his subject, Neuroses of the Viscera.

Allbutt remained at Leeds, working at the highest possible pressure until 1889, discharging his official duties, enlarging his private responsibilities, and resolutely informing his colleagues by papers, lectures, and addresses, dealing with an ever-expanding range of clinical subjects. It must be remembered here that consulting practice in Yorkshire 35 years ago was physically a strenuous affair if calls abroad were frequent from the outlying districts, and at length Allbutt had to confess to himself that he was overtaxing his strength. Many offers are known to have been made to him to return to London in various dignified capacities, but these he had so promptly refused that some surprise was manifested when at this time he accepted the post of Commissioner in Lunacy. This he held for three years, and his knowledge of affairs as much as his experience of the sick made of a wise and kind man a satisfactory official, but those who knew what were his aspirations fully endorsed the action of the authorities in choosing him

as successor to Sir George Paget as Regius Professor of Physic in the University of Cambridge.

At Cambridge, although well over 50 years of age and without any experience either as university professor or college don, he immediately took his place in the front of academic life. He had a remarkably flexible mind, which was readily appreciative of the work of others, a very necessary quality in a university professorship. He was also progressive in his views and untiring in keeping abreast with new work, and thus his big but exact store of information usually enabled him to standardise as important, or as interesting, or as negligible, with discriminating judgment; but his attitude towards all honest work was so invariably sympathetic that even when he felt unable to commend the result he was often able to encourage the worker, and to indicate to him where his labours might bear fruit. (Hundreds of workers, some no longer young, will endorse this from personal experience.) Almost immediately after succeeding to his Chair he projected the scheme for a new system of medicine, whose outcome, more than his great clinical record, will keep his name alive. Accordingly in 1896 there began to appear the first edition of Allbutt's *System of Medicine by Many Writers*, dedicated to Sir Russell Reynolds, whose similar but very unequal system had fallen into disuse. The work was immediately triumphant, and the second edition, which we now all use, was issued under the editorship of himself and Sir Humphry Rolleston some ten years later. It would be difficult to estimate the benefit which the undertaking has been to medicine all the world over. To the *System of Medicine* Allbutt contributed considerably, writing the sections upon the history of medicine, on neuroses and dilatation of the stomach, on chlorosis, neurasthenia, and, most importantly, on cardiac diseases, overstress and functional disorders of the heart, and diseases of the aortic area. He also contributed a chapter on mountain sickness from the point of view of an experienced Alpine climber. From the inception of the undertaking he spared no trouble in maintaining the symmetrical form of the compendium, ensuring the authoritative nature of the contributions and watching over the literary style. The policy was continued with the second edition, and the scrupulous care was even perfected under the joint editorship of Allbutt and Rolleston. Those who have had occasion to look further into any subject than such a summarising chapter as in many cases is all that the best compendium need attempt to supply, will realise the unlimited aid which they obtain from the long list of references appended to most of the chapters, given in such a form that their verification is possible.

As was inevitable, his position at Cambridge made him an intimate observer of all phases of modern medical education, and his words on the proper place of the teaching of universities in the medical curricula were always weighty. He wrote on several occasions to these columns useful and pointed explanations of the need for the establishment of clinical units, foreseeing in them that blend of theory and practice which his whole life was spent in exemplifying.

To attempt a résumé of Clifford Allbutt's literary output would not only be difficult but unnecessary. For almost from the beginning of his career he was one of those who not only knew what he wanted to say, but knew what wanted to be said, so that his various addresses in a clinical or official capacity always possessed two qualities, apart from literary charm, which have ensured their recollection. In the first they were arresting from their topicality, but secondly they remained as sources of inspiration because of their broad outlook. Take, for example, such an address as that in medicine which he delivered at the annual meeting of the British Medical Association in Glasgow on the *Classification of Diseases by Means of Comparative Nosology*. From a wide range of reading and observation he indicated that the marshalling of diseases of men, animals, and plants on various bases of affinity must pursue at least four different methods of inquiry—the hereditary, the historical, the geo-

graphical, and the experimental—and although, under each of these headings, during the more than thirty years that have elapsed, subdivisions and refinements have made their appearance, the scheme laid down by Allbutt remains inclusive and fruitful, for the present interest in comparative pathology dates definitely from that address. Another example of the permanent utility of Allbutt's deliverances is furnished by his "Notes on the Composition of Scientific Papers." No doubt much writing on his own part, and certainly much editing of the writing of others, had revealed to him certain common pitfalls in English prose into which not only the careless or the ill-educated, but even industrious and learned writers might fall. Not since Dean Alford wrote "The Queen's English" has any more valuable guide to the art of writing and arranging written matter been published, and the practical value of the essay is proved by the fact that a third edition appeared only a few months ago. And a sidelight on the continuity of his interests is shown when he chose for the subject of the FitzPatrick Lectures at the Royal College of Physicians of London the subject of Greek Medicine in Rome. His words synchronised with the growing feeling that the bases of our ancient professional learning might be studied with advantage, not so much out of historical curiosity, but in order to show, for future edification, how systems and schools of thought arise, and how their votaries make good in some directions, and how the unimportant as well as the incorrect fall gradually away from the store of knowledge, leaving us what is valuable whereon to base future developments. It was along such broad and fundamental lines that Allbutt's mind ever worked.

To enumerate the degrees which Allbutt earned or received would require much space, if it were to be done in detail; but this is here unnecessary, so familiar are all our readers with the great position which he occupied. He was, we believe, the only medical man who was ever summoned to the Privy Council as a medical man. At the Royal Society he served on the Council as Vice-President; he was a D.Sc. in three universities, and an LL.D. in five; he held the honorary Fellowship of several Colleges and Academies; he was a K.C.B., and a Justice of the Peace for two counties. He had held examinerships at different times in the University of Oxford and the Royal College of Physicians of London, where he delivered, as has been said, the Goulstonian Lectures and the FitzPatrick Lecture, and was also Harveian orator. At the College he was at different times on the Council and a Censor. He was President of the British Medical Association in the strenuous days of the war and an honorary Lieut.-Colonel in the Royal Army Medical Corps. We do not exhaust the list of honours that might be enumerated, but no more emphasis need be laid on them. Throughout his life he grudged no man any success, so the wide recognition which his own services and gifts received was always felt by the medical profession as fitting. He was learned without pedantry, firm but even-tempered, courteous but unaffected, on occasion a good orator, and always an admirable talker, whose wit was unstudied and whose excursions into a diversified range of subjects were as often as not taken in order to exhibit the familiarity of others with these subjects.

Sir Humphry Rolleston, Bart., K.C.B., President of the Royal College of Physicians of London, writes:—

"A friend of my father, Sir Clifford Allbutt had for more than 30 years constantly helped me in innumerable ways, and his sudden death is an irreparable and unexpected break in the established order of things. For though he was in his eighty-ninth year he was astonishingly young for his length of days, the main or only evidence of age being deafness. In his full sympathy with the young and with fresh ideas and in his broad outlook he indeed compared favourably with many a man of half his years. Aristocratic in appearance and courtly in manner—somewhat resembling the great Lord Dufferin—he was the most approachable of men; obviously a great gentleman, he had indeed a genius for friendship, and I never

SIR CLIFFORD ALLBUTT

THE LIBRARY
OF THE
UNIVERSITY OF ILLINOIS

heard him speak ill of anyone, though he shrewdly estimated the points of character. Like Sir Henry Acland, the Regius Professor of Medicine at Oxford, he had a refreshingly wide and original outlook on medicine, and was more concerned with principles than details. Among his many activities reference may be made to two: his general influence on medical education and culture, and the special subjects in which he initiated advances. He was a scholar in the broadest sense, a profound medical historian, an omnivorous reader, and a persistent advocate of the need for a sound general education as the basis of medical training. With a highly critical literary taste, he was as careful in his own writings as he urged others to be in the choice and use of words. But he was far more than a scholar or a learned man, for his combination of wisdom, humanity, and versatility was of a kind that appears to be dying out in a world that has seen many changes in a comparatively short time. His public addresses were on broad lines and fearlessly independent. Thus, in the Goulstonian Lectures for 1884 he satirised the vagaries of the contemporary gynaecologist with a masterly touch, and later, in 1920, expressed his stern disapproval of the practice of psycho-analysis; while in the St. Louis address on the historical relations of medicine and surgery (1905) he insisted on the present artificial distinction between the surgeon and the physician. Since his address in medicine at the Glasgow meeting of the British Medical Association in 1888 he had urged the recognition of comparative pathology, and it is a happy outcome of his appeals that there is now an institute for this branch of research at Cambridge and a section for its study at the Royal Society of Medicine, of which he was appropriately the first President. No one could write more charmingly of others, as is shown to perfection by his introduction to the volumes dedicated to the late Sir William Osler (1919) and to Karl Sudhoff (1924) on their seventieth birthdays.

"He rapidly formed a sound judgment on new work, and was ever alert to welcome the germ of a real advance; thus, in his review (*Brit. Med. Jour.*, 1902, ii., 259) of the book on the pulse by the then little known James Mackenzie of Burnley he generously described it as destined to 'take a permanent place in the standard records of the subject.' It is indeed remarkable how many matters of now common knowledge in medicine he either originated or made more widely known, though in some instances his share therein has from lapse of time been perhaps naturally forgotten. For many years he described hyperpiesia—or, as he originally called it, senile plethora (1895)—and while so doing was largely responsible for the introduction of the sphygmomanometer into ordinary practice. His advocacy of the aortic origin of angina pectoris dated from 1894, and those who heard him speak after Prof. K. F. Wenckebach's lecture on angina pectoris and the possibilities of its surgical relief at the Royal College of Physicians on May 5th, 1924, were impressed with his mental and physical vigour. He was one of the first, if not the first, to describe syphilitic disease of the cerebral arteries (1868); he was the first in this country to record a case of tabetic arthropathy, a year after Charcot's description in 1868; and he early insisted on the effects of strain on the heart and arteries (1870), on the value of morphine in cardiac disease (1869), on the use of the stomach pump, and of the ophthalmoscope in medicine (1871). Together with the late Mr. Pridgin Teale he advocated the operative treatment of tuberculous glands in the neck (1885), and in 1867 he invented the present short form of clinical thermometer.

"Such are a few achievements of the philosopher, the professor, and the physician; but greater even than them were the character and personal influence of the man, the like of whom his friends can hardly hope to see again. He died as he would have wished in the full tide of his activities; he was to have given the Lloyd Roberts Lecture at the Royal Society of Medicine this autumn, and had a new book ready

for the press. Our sorrow is for those left behind; for him there is no feeling but of thankfulness that he had lived so fully and so finely right up to the inevitable end."

Sir Thomas Clifford Allbutt married in 1869 Susan, daughter of the late Thomas England, of Headingley, by whom he had no children. To his widow the sympathy of the whole medical profession is extended. He was buried at Trumpington, near Cambridge, on Wednesday last, the funeral services, which were largely attended, being held in the Chapel of Gonville and Caius College, of which he was a Fellow, and in Great St. Mary's, the University Church.

EPHRAIM MACDOWEL COSGRAVE, A.B., M.D.
DUB., M.Ch., F.R.C.P. IREL.

Dr. MacDowel Cosgrave, past President of the Royal College of Physicians of Ireland, died in Dublin on Feb. 16th after some weeks' illness at the age of 71. He enjoyed good health until a month before his death, when a slight cerebral hæmorrhage occurred. He appeared to rally, and his friends hoped that he might still have some years to live, but it was not so to be. Dr. Cosgrave was educated at Trinity College, Dublin, and proceeded to his medical degrees in 1876. In 1886 he was appointed lecturer in botany in the Carmichael School, and on the amalgamation of that school with the school of the Royal College of Surgeons three years later he became professor of biology in the latter. He continued to perform the duties of that office to the time of his death. In 1887 he became a Fellow of the Royal College of Physicians of Ireland, and in 1914 was elected President of the College. Dr. Cosgrave was not attached to any of the general clinical hospitals, but he was for many years physician to Drumcondra Hospital, and had also been physician to Cork-street Fever Hospital, and during the war to the Dublin Castle Red Cross Hospital. He was a knight and honorary associate of the Order of Hospitals of St. John of Jerusalem in England, and an examiner and lecturer to the St. John Ambulance Association. He was also a member of several Dublin scientific societies, and at one time filled the office of physician-in-ordinary to the Lord Lieutenant of Ireland.

Among his medical writings he published a treatise on Hints and Helps for Home Nursing and Hygiene, which achieved great popularity, and in 1885 "The Student's Botany," while in 1899 appeared "The Role of Alcohol."

Dr. Cosgrave made a special study of the history and antiquities of Dublin, and he was an authority on everything relating to Georgian Dublin. He wrote or edited several books on this topic, including a "Catalogue of Engravings of Dublin," an "Illustrated Dictionary of Dublin," and the publications of the Georgian Society. He had himself a valuable and charming collection of furniture, engravings, books, and book-plates. Dr. Cosgrave was a conscientious and careful physician, courteous and gentle in manner, and a man of charm and culture.

SUSSEX THROAT AND EAR HOSPITAL.—In connexion with the scheme to extend the out-patients' department of the hospital at Brighton, it was stated at the forty-sixth annual meeting, held recently, that although over £900 had now been subscribed, no extensions would be undertaken until the full estimated cost of £2000 was assured. Improvements carried out during the past year included a new and thoroughly efficient sterilising room, kindly provided by Major R. L. Thorntor, and a new operating table. Financially, the treasurer stated, there was hardly any debt on the year's working. Of the income from ordinary sources, apart from rents and invested funds, the payments from patients amounted to £976 19s. 2d., which was more than half the total. Among the contributions was £163 from friendly, trade, and other societies. The hospital joined the Sussex Provident Scheme during the year and received £75 from it. Lord Leonfield presided over the meeting.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. J. E. Clark to be Surg. Lt.-Comdr.

ROYAL NAVAL VOLUNTEER RESERVE.

W. E. M. Wardill to be Surg.-Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. J. Dorgan retires on retd. pay.

RESERVE OF OFFICERS.

Maj. S. W. Sweetnam, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Col. T. Kay (late R.A.M.C., T.A.) to be Col. and Asst. Dir. of Medical Services 52nd (Lowland) Division T.A., vice Col. G. H. Edginton, who vacates on completion of tenure of appointment.

Lt.-Col. (Bt. Col.) F. Whalley, from R.A.M.C., T.A., to be Col. and Asst. Dir. of Med. Services 49th (West Riding) Division T.A., vice Col. A. D. Sharp, who vacates on completion of tenure of appointment.

Lt.-Col. (Bt. Col.) R. E. Bickerton, from R.A.M.C., T.A., to be Col. and Asst. Dir. of Med. Services 56th (1st London) Div. T.A., vice Col. A. D. Ducat, who vacates on completion of tenure of appointment.

YEOMANRY.

Supernumerary for Service with O.T.C.—Capt. A. Fowler (late R.A.M.C., S.R.) to be Capt. for service with the Medical Unit Aberdeen University Contingent, O.T.C.

INDIAN MEDICAL SERVICE.

The King has approved of the resignation of his commission by Capt. A. L. Watts.

PAY OF INDIAN MEDICAL SERVICE OFFICERS IN MILITARY EMPLOY.

The Secretary of State for India has sanctioned the extension to Indian Medical Service Officers in military employ of the concessions regarding overseas pay recently introduced for officers of the Indian Medical Service in civil employ. The extension has effect from April 1st, 1924. Officers now in the United Kingdom who have been in receipt of rupee rates of pay for any period after this date, and who accordingly have claims for retrospective adjustment under this concession, should address the Controller of Military Accounts by whom they were last paid in India.

Passage concessions have been sanctioned for officers of the Indian Military Services. They will apply to any passage beginning on or after Feb. 14th. Detailed rules have yet to be drawn up, but the provisional arrangements which have been approved are being communicated by the India Office to all officers concerned who are now under the orders of the India Office.

THE WEST AFRICAN MEDICAL STAFF.

A new edition of the West African Medical Staff List, corrected up to Jan. 31st of this year, has just been issued from the Crown Agents for the Colonies, 4, Millbank, Westminster, London, S.W. It contains a list of officers in grades with their dates of appointment, a list of officers arranged by colonies, and an alphabetical list with qualifications and services.

THE GOLDEN BOOK OF THE ROYAL ARMY MEDICAL CORPS.

On July 13th, 1922, a tablet to the memory of 743 officers and 6130 warrant officers, non-commissioned officers, and men of the Royal Army Medical Corps was erected in Westminster Abbey. The names of the fallen are enrolled in a Golden Book which will shortly be placed in the Chapter House of the Abbey. A reproduction of the list, which gives the names in alphabetical order with the date of death, and an indication as to whether the soldier died in action or of wounds, has now been issued for the relatives and friends at the price of 2s. 6d. by Messrs. Charles Whittingham and Griggs, Ltd., 20, Took's-court, Chancery-lane, London, E.C.

RONTGEN SOCIETY.—A general meeting of this society will be held on Tuesday, March 3rd, at 8.15 P.M., in the British Institute of Radiology, 32, Welbeck-street, London, W. A paper on the Photometry of Fluorescent Screens will be read by Dr. Leonard A. Levy, D.Sc., and Mr. D. W. West.

Correspondence.

"Audi alteram partem."

ALKALIS IN CERTAIN DISEASES OF THE SKIN.

To the Editor of THE LANCET.

SIR,—In respect of Dr. F. Carminow Doble's article in your issue of Feb. 7th may I report the following case? A patient of mine had been troubled for many years with patches of eczema breaking out on the outer surfaces of his limbs, not large themselves, but setting up large areas of itching; a patch not larger than a shilling would set the whole forearm afire. Or, again, likewise for the leg or thigh. He had found that this scourge happened in the winter only, and accordingly traced it to the effects of fire heat; thus by careful avoidance of the fire, or the use of a screen, he managed with some, but not complete, success to mitigate his plague. The best curative means were simple unguents-inunction with olive oil after the bath, "cold cream," or "glycerine and honey." In the summers he was almost free. His next trouble was nocturnal micturition. As his urine always had been highly lithatic, always painting the chamber-pot, I advised him to take a small teaspoonful of sodium bicarbonate at bedtime. As this put the micturition right the evening alkali was regularly taken. In two or three weeks the patient observed that his eczema had ceased, and with ordinary care he escaped the fire irritation; the unguents lay neglected on the shelf. Two winters have now passed without eczema, and the limbs can be towelled without irritation. The change is remarkably complete; indeed, the patient says that the skin of his limbs is much more "natural," softer, and more pliant to the touch. I offer to Dr. Doble and your readers no explanation, simply an empirical result.—I am, Sir, yours faithfully,

Cambridge, Feb. 17th, 1925.

CLIFFORD ALLBUTT.

HYGIENE OF THE NOSE AND NASO-PHARYNX.

To the Editor of THE LANCET.

SIR,—No more opportune moment could be found than the present one for discussing this subject, when the whole world is being attacked by that most insidious and mysterious of all diseases that are air-borne—viz., influenza. Your readers should be grateful for your calling attention to it in a leading article (vide THE LANCET, Feb. 14th, p. 344).

The medical student has but little time, unfortunately, to study the details of the anatomy of the nose with its vast intricacies, nor of its physiology, and there is practically no instruction given in the hygiene of the healthy nose. It is possible, then, that some of your remarks may lend themselves to be misinterpreted.

The objection to the removal of any part of the surface of the interior of the nose is not peculiar to that organ, since scar-tissue can never function like normal tissue. Also when waste is removed regularly the surface of any organ is likely to remain healthy. But life in the open air will not supply the deficiencies that must be due to lack of care of every sort. Some of the worst cases of sinus disease that have come under my notice have occurred in professional gardeners. It is hardly safe to hold that catarrh is incompatible with the simple life unless that includes the natural methods of the animals that have breathing organs of the same plan as our own—i.e., the keeping of them clean and clear and free from any accumulation of waste. There is some danger in cleaning the nostrils of an infant with pledgets of cotton-wool. The slightest excess of force may drive in the little plugs of dust and dried secretions which lodge in

the nostrils or through the narrow slits which guard the interior of the nasal passages and cause an obstruction which a delicate infant will not be able to shift.

The danger of forcing toxic material into the Eustachian tube is well recognised. It is not so great when one nostril only is closed when blowing the nose, as when there is no airway left in either, but it is sufficiently great specially to be guarded against. The discharges not being able to escape freely are forced up towards the organs among which the nose lies and with which it is in anatomical and physiological continuity and damage is likely to occur to some of them. For the same reason sniffing is a dangerous as well as unpleasant habit. It cannot, however, be seriously suggested that as a suitable alternative the stagnant secretions should be swallowed. The stomach cannot be asked to take on the rôle of a dustbin without interfering with its proper functions. Constant swallowing of anything upsets the rhythm of respiration and when the material swallowed is highly undesirable putrid waste such as develops in chronic catarrh there can occur nothing but harm.

The difficulty of securing the services of anyone who can be trusted to irrigate an infant's nose and know exactly when to stop would suggest that it is a practice not to be encouraged. One case has been brought to my notice where the child succumbed in the nurse's arms, as the exceptional skill and experience were wanting. Nor is it likely that the child who is clogged will have the accuracy of touch to irrigate its nose safely. The child who cannot blow the nose should be trained in the art. The "unkempt" nose is a danger to its owner and to his companions. Handkerchief drill is already established in some schools with the greatest benefit to all concerned.

I am, Sir, yours faithfully,

OCTAVIA LEWIN, M.B., B.S. Lond.

Wimpole-street, W., Feb. 20th, 1925.

THE ACIDIC VALUE OF THE URINE IN SKIN DISEASES AND OTHER CONDITIONS.

To the Editor of THE LANCET.

SIR,—If, as Dr. H. W. Barber admits in his letter in your last issue, the urine is sometimes hypacid, and there is no evidence of acidosis in the blood, I do not see why one should be tempted to try alkalies. Dr. Barber states that the urine may become very acid and the patients show a high alkali tolerance. It would be interesting to know what controls he has carried out on apparently normal people.

However, the chief reason for this letter is to explain that having failed to corroborate his theory by control work I was not deterred from trying the therapeutic test. In many cases valuable discoveries have been made working on a theory which has been found subsequently not to be the right one, and an admirable instance of this is found in the Wassermann reaction for syphilis. None of my patients were improved by making their urine strongly alkaline and for some time after the publication of Drs. Barber's and Semon's paper I was constantly seeing patients with highly alkaline urine resulting from their having been placed upon Dr. Barber's prescription.

Dr. Barber admits that others have been unable to corroborate his work, but says there is no doubt that it is right. I would point out that Dr. Doble disagrees with him in that Dr. Doble thinks it is not enough to produce alkalinity, but that it is necessary to produce only a certain degree, otherwise the condition is not cured.

Dr. Semon, since the publication of the paper in which he was associated with Dr. Barber, has published another recommending X rays for acne, a disease which I am sure Dr. Barber will agree with me in regarding as lying on a foundation of seborrhoea; so that apparently Dr. Semon has not

found the alkaline treatment alone sufficient. Are we then to accept a theory based on results which we cannot corroborate and to continue a form of treatment which in our hands and the hands of others has proved futile?

I am, Sir, yours faithfully.

ARTHUR WHITFIELD.

Harley-street, W., Feb. 23rd, 1925.

UNILATERAL PHRENIC NERVE PARALYSIS.

To the Editor of THE LANCET.

SIR,—Sir Charlton Briscoe's article on this subject in THE LANCET of Feb. 21st is of particular interest because of the renewed attention to artificial paralysis of one half of the diaphragm, now that the operation of phrenic evulsion has been substituted for that of phrenicotomy.

The symptoms of "phrenic paralysis" due to morbid lesions are evidently very different from those which follow phrenic evulsion. I have recently done this operation on six patients and the total absence of any post-operative symptoms has been most surprising. When the nerve is first seized in the forceps (a local analgesia only is used), there is a twitch of the corresponding half of the diaphragm visible to the onlookers, and felt as such by the patient. When the nerve gives way, whether intrathoracically at some 10 to 20 cm. distant, or by actual evulsion of the fibres from the diaphragm, the relaxation of the strain is also felt, but no pain whatsoever.

After this there have been no symptoms, neither pain, respiratory distress, nor preference for any particular posture. The only difference felt referable to the altered position of the diaphragm has been the sensation of a hollow under the right costal margin in one patient, in whom there has been considerable elevation of the dome and of the liver. In every case the disappearance of the dry reiterated purposeless cough has been remarkable.

I am, Sir, yours faithfully,

H. MORRISTON DAVIES.

Vale of Clwyd Sanatorium, Feb. 21st, 1925.

TINCTURE OF IODINE (PH. FR.).

To the Editor of THE LANCET.

SIR,—In your issue of Feb. 21st Dr. P. C. Brett states that the change in the formula for tincture of iodine (Codex 1908) made in the French Codex of 1922 has not been published in medical literature. The following paragraphs appeared in an editorial in the *Prescriber* of February, 1923, p. 64, dealing with iodine as an internal remedy:—

"... Since that time, however, a further difficulty has arisen, which will nullify all the recommendations made of this [French Codex] tincture. *The French Codex has altered the formula.* Under the name of 'Tinctura Iodi Iodurata,' a new preparation appears in the Codex Supplement 1920, which contains iodine, 30 grains, and potass. iod., 12 grains, in one fluid ounce of alcohol 90 per cent., and this preparation is to take the place of the old Codex tincture. The new formula entirely defeats the object of the intensive iodine treatment, which is to administer iodine to the amount of tolerance without KI. This cannot be done with the new tincture, which will of course be supplied if 'Tinct. iodi. French Codex' be prescribed, and physicians must note this and cease to specify 'French Codex.'

"In the absence of a suitable official preparation we would suggest the use of the *Tinctura Iodinei* of the old Edinburgh Pharmacopœia. This contains one grain of iodine in 16 minims of rectified spirit, without KI, and is still kept in stock by many pharmacists north of the Tweed. It is 50 per cent. weaker than the old French Codex preparation, but as dosage is not definitely laid down, being entirely a matter of tolerance, the instructions will be to begin with 2 or 3 minims and gradually increase so long as no iodism is produced. Boudreau observed that one of his patients was able to take 350 drops (not minims) in 24 hours for a month. ..."

I am, Sir, yours faithfully,

THOMAS STEPHENSON,

Editor of the *Prescriber*.

Edinburgh, Feb. 21st, 1925.

MEDICAL AID FOR THE RIFFIS.

To the Editor of THE LANCET.

SIR.—In the House of Commons last week Mr. Saklatvala asked the Prime Minister if it was the intention of the Government to continue the policy of the former Government or whether it will support an appeal of the British Red Crescent Society to the French and Spanish Governments to give facilities for sending a medical mission and medical supplies for the Riffis. For it was reported that the sick and wounded were without medical aid, although Article 2 of The Hague Convention (Laws and Customs of War on the Land) gave belligerent rights to fighting men in a *levee en masse* of the population, providing that they carried their weapons openly and conformed to the laws and usages of war. Mr. Austen Chamberlain (Secretary of State for Foreign Affairs) replied to the effect that the Government were not prepared to intervene in a matter which was entirely a question for the Spanish and French Governments. He further stated, that by Article 2 of The Hague Convention, the provisions of the land warfare regulations apply only as between the signatory parties, and that even if the insurgent tribes in the Spanish and French protectorates were signatories, that the sending of a medical mission or medical supplies to the Riffis have nothing to do with the land warfare regulations.

With the passing remark that Mr. Saklatvala's question was neither inspired directly or indirectly by the Red Crescent Society, one must confess that it is difficult to conceive how an official in the position of Mr. Chamberlain could ever have returned any other reply. But this by no means disposes of British responsibility in the matter. There is an insistent cry from our Moslem fellow-subjects in India that the sufferings of their co-religionists in the Riff should not be disregarded. With unanswerable logic they point out what a clamour would arise in England if a tiny Christian community struggling for freedom against a Mohammedan power were to be deprived of all medical assistance. Some of us are inclined to listen to their cry. We remember with gratitude how the Moslem chivalry of India drew their swords in the Great War and proved their traditional valour on the battlefields of France, Mesopotamia, and Palestine. Many were killed, and lie for all time in honoured graves, while those who were wounded or "gassed" remember their sufferings and wonder what would have been their fate had they been deprived of medical assistance in their hour of need. They read in the papers how the people of the Riff are being assailed with all the latest diabolical contrivances of war—shell, bomb, and poison gas—and the poorest of the poor have subscribed their mites to help the victims. It is a supreme pity that Spain will not see her way to concede to a society working solely in the interests of humanity the right to send a hospital unit. It would be a valuable witness to the fact that Spain was conducting the war in accordance with regulations, and would also be a comfort and protection to the Spanish prisoners in the hands of the Riffis: for the British Red Crescent Society, although founded primarily for the relief of Moslem victims of war, does not work in any mean or sectarian spirit. The President, the Rt. Hon. Syed Ameer Ali, who has had a long and distinguished career in the service of the King-Emperor, has always made this clear. I well remember that before my departure for the Turco-Italian war in Tripolitana, he strictly enjoined me that I was on no account to allow differences of religion or nationality to prejudice me in granting relief, with the result that Christian, Moslem, and Jew shared alike in the charity we administered.

Finally, it must not be thought that those of us who advocate the sending of medical relief to the Riff are in any sense hostile to the Spanish people. We recognise the valour of the Spanish troops who are battling in a country more difficult to fight in than Switzerland or Montenegro, and we regret that

treasure should be poured out in an attempt to subjugate a gallant little people, while the fertile soil and vast mineral treasures of Spain are left neglected. Surely if Great Britain, backed by the enormous resources of the Empire could afford to grant a practical independence to Ireland, Spain need feel no humiliation in granting the status of a dominion to Abdul Kerim's people. But that is hardly a medical question.

I am, Sir, yours faithfully,

ERNEST H. GRIFFIN.

48, Upper Berkeley-street, Portman-square, W. 1,
Feb. 24th, 1925.

ASSOCIATION WITH UNQUALIFIED PERSONS.

To the Editor of THE LANCET.

SIR,—From letters which I have received I gather that some practitioners are in doubt as to the bearing of the following paragraph in the Warning Notice issued by the Council:—

"5. Association with Unqualified Persons.

"Any registered medical practitioner who, either by administering anæsthetics or otherwise, assists an unqualified or unregistered person to attend, treat, or perform an operation upon any other person, in respect of matters requiring professional discretion or skill, will be liable on proof of the facts to have his name erased from the Medical Register."

I am directed to say that this warning does not apply to any person whose name appears upon the Dentists Register, whether so entered in virtue of a diploma or under the Dentists Act, 1921. A registered medical practitioner is entirely at liberty to give an anæsthetic for such a dentist.

I think it might be helpful if the attention of medical practitioners was drawn to their position in regard to this matter.

I am, Sir, yours faithfully,

NORMAN C. KING,

Registrar, General Council of Medical Education and
Registration of the United Kingdom.

Feb. 24th, 1925.

COLOUR IN ANIMALS.

To the Editor of THE LANCET.

SIR.—It might be of interest to those biologists engaged in the study of colour in animals (Mr. J. Barcroft will shortly give three lectures on this subject at the Royal Institution) to bear in mind the paradoxical pupil reaction. The discovery that after section of one sciatic nerve paradoxical effects appear in the contralateral eye about the twelfth day was in itself remarkable. But the further discovery that any section or injury of a nerve is reflected in the pupil reactions, proving thereby an intimate functional relationship between the efferent portion of the pupil-dilator mechanism and every portion of the periphery through the medium of the sensory nerves, suggests that possibly the explanation so eagerly sought for, the law governing the adaptation of colour in animals to their surroundings, lies in this direction. It is in full support of the fact that blinded frogs and chameleons lose this power of adaptation of the colour of their skins to their surroundings.

I am, Sir, yours faithfully,

HORATIO MATTHEWS, M.D.

Harley-street, W., Feb. 6th, 1925.

ROYAL SANITARY INSTITUTE.—A sessional meeting of the Institute will be held on Friday and Saturday, March 6th and 7th, in the Town Hall, Halifax, when discussions will take place on the Working of the Milk and Dairies (Amendment) Act, 1922, to be opened by Mr. John Pollard, M.R.C.V.S., and on Some Food Dangers by Mr. H. T. Lea. The chair will be taken at 4 P.M. on Friday by Prof. A. Bostock Hill. Those proposing to attend the reception, luncheon, and visits in connexion with the meeting should notify the hon. local secretary, Dr. Cyril Banks, Town Hall, Halifax, not later than Monday, March 2nd.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—J. H. Clapp, London Hosp.; J. L. Hopkins, Guy's Hosp.; O. W. Percival, London Hosp.; C. C. Po, Guy's Hosp.; J. Shutt, Leeds and London Hosp.; R. F. Stubbs, Manchester; and B. Temple-Raston, St. Mary's Hosp.

Medicine.—K. V. Mead, St. Thomas's Hosp.; C. C. Po and P. B. Skeels, Guy's Hosp.; B. L. Steele, Univ. Coll. Hosp.; and R. F. Stubbs, Manchester.

Forensic Medicine.—A. Henson, Charing Cross Hosp.; K. V. Mead, St. Thomas's Hosp.; T. K. Natesan, London Hosp.; and R. F. Stubbs, Manchester.

Midwifery.—N. E. Challenger, McGill; T. K. Natesan, London Hosp.; O. W. Percival, Sidney; C. C. Po, Guy's Hosp.; J. Shutt, Leeds and London Hosp.; B. Temple-Raston, St. Mary's Hosp.; I. Waynik, Charing Cross Hosp.; and G. H. Weeber, Middlesex Hosp.

UNIVERSITY OF BRISTOL.—At examinations held recently the following candidates were successful:—

FINAL EXAMINATION FOR DEGREES OF M.B., CH.B.

Part II., with Second-class Honours.—Dorothy E. Crellin, distinction in medicine; Constance Irene Ham, distinction in surgery and obstetrics; Arthur H. Lowther, distinction in pathology and obstetrics; and Rosalie E. Lucas, distinction in medicine.

Pass.—Arthur F. Alford, Kenneth F. Alford, Alexander S. Cox, Sidney J. H. Griffiths, Frederick E. Hollingshead, John A. Hooker, Kenneth F. Platt, David C. Prowse, Lennox G. Robertson (distinction in obstetrics), Herbert Rogers, Gertrude M. Terrell, and Maria M. Tewater.

In Medicine (completing Examination).—Ernest R. Clutterbuck.

In Surgery (completing Examination).—Helen M. Dixon.

In Public Health (completing Examination).—Arthur H. Marshall.

In Group I. only (Surgery and Obstetrics).—Elizabeth E. Benson, Margaret P. Posthuma, Herbert J. Satchwell, and Kathleen M. Willmore.

In Group II. only (Pathology, Medicine, and Public Health).—Charles F. Rowe Killick.

Part I. (including Forensic Medicine and Toxicology).—Geoffrey W. R. Bishop, John F. O. Bodman, Muriel E. Drew, Francis S. Dymond, George L. Feneley, Francis R. Gedye, Arthur P. Gorham, Mildred B. Harvey, Thomas P. Lalonde, Maurice E. J. Packer, Charles B. Perry, Leslie B. Phillips, Ernest S. Rogers, and Arthur A. B. Vincent.

EXAMINATION FOR DIPLOMA IN PUBLIC HEALTH.

Vincent Ryan.

In Part II. (completing Examination).—John Ledingham.

In Part I. only.—Nora A. McD. Rodger and William W. S. Sharpe.

UNIVERSITY OF LONDON.—A course of four lectures on Puerperal Sepsis will be given in the lecture theatre at St. Thomas's Hospital Medical School (Albert Embankment, S.E.) by Prof. B. P. Watson, at 5 p.m. on March 2nd, 3rd, 4th, and 5th. At the first lecture the chair will be taken by Dr. H. Russell Andrews. Admission free.—A course of two lectures on Vital Statistics will be given at University College by Prof. Harald Westergaard, at 5.30 p.m., on March 9th and 11th. The lectures will be delivered in English. Admission free.

University College.—A special course for the Primary Fellowship of the Royal College of Surgeons of England, in preparation for the June examination, will begin at University College, Gower-street, London, W.C., on Monday, March 2nd.

UNIVERSITY OF LEEDS.—Dr. T. Wardrop Griffith has placed before the Council of the University his resignation of the professorship of medicine. In his letter he points out that, in harmony with the rules of the Leeds General Infirmary, he becomes a member of the consulting staff next September, by which date he will have served for 20 years on the full staff. It was this fact which had led him to anticipate the age-limit for the tenure of office which attaches to professorships in the University; for, although members of the consulting staff have the privilege of admitting a limited number of patients to be under their care in the infirmary and continue to work within its walls, he felt that the best interests of the University would be served if the professor of medicine occupied a position on the full staff. At the meeting of the University Council on Feb. 18th a resolution was adopted, in which the resignation of Prof. Griffith was accepted with deep regret, and a fitting tribute was paid to his work for the University. Prof. Griffith was senior professor at the Leeds Medical School. He was appointed to the chair of Anatomy in 1887 and transferred to the chair of Medicine in 1910, a continuous record of 38 years. In both departments his courses of lectures have been notable for their vivid quality and the perfection of arrangement and delivery. His work in the chair of Medicine has been acknowledged by his admission to the Order of St. Michael and St. George and the conferment of the honorary doctorate of Laws by his own University of Aberdeen.

HUNTERIAN SOCIETY.—The Hunterian Oration on Angio-hæmic Anæmia will be delivered by Dr. H. Letheby Tidy, on March 2nd, at 9 p.m., at the Mansion House.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The Milroy Lectures will be delivered on March 5th, 10th, and 12th at 5 o'clock at the College, Pall Mall East, S.W., by Dr. Salusbury MacNalty on Epidemic Diseases of the Central Nervous System. Any member of the medical profession will be admitted on presentation of card.

INTERCHANGE OF HEALTH OFFICERS.—On the recommendation of the Society of Medical Officers of Health, the Ministry of Health have nominated Dr. James Fenton, M.O.H. for Kensington, and Dr. Alfred Greenwood, M.O.H. for Kent, for the interchange of health officers to be held in Jugo-Slavia during May and June next, under the auspices of the Health Section of the League of Nations. For the interchange to be held in Belgium about the same time the Society recommended Dr. R. J. Maule Horne, M.O.H. for Poole, who has been duly nominated by the Ministry. On the recommendation of the Chief Medical Officer of the Ministry of Home Affairs of Northern Ireland, the Ministry of Health have also nominated Dr. Norman C. Patrick for the Belgian interchange.

MEDICAL TOURS IN MOROCCO.—The French Compagnie Transatlantique is organising two new tours in Morocco for medical men and their families. The first tour will start from Bordeaux on March 30th, and will terminate on April 30th at Marseilles. The second will start from Marseilles on April 18th, and will finish at Bordeaux on May 14th. The journey through Algeria and Morocco will embrace all the places of interest from Algiers to Marakesh, and the entire transport will be by motor-car, each vehicle seating ten passengers. The cost of the tour is 4800 French francs per head. Further information may be obtained from Dr. Victor Gardette, 3, rue Alexandre de Humboldt, Paris (XIV.), who is undertaking the arrangements of the tours.

PUBLIC HEALTH STUDY.—The next interchange of public health officials to be organised by the League of Nations will take place early in March, when ten medical officers from the Republics of South America will meet in Cuba and spend the succeeding months until August in a tour of study arranged by the public health authorities of the United States, Canada, and various European countries. These officials will study the general character of the health organisations of the United States, Canada, and England, and on the continent of Europe several types of organisations where particularly striking results have been obtained.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A discussion on post-graduate teaching in London has been arranged to take place at 1, Wimpole-street, on Wednesday, March 18th, at 6 p.m. Sir Arbuthnot Lane, President of the Fellowship, will preside, and all members of the medical profession in London are invited to attend and to give their criticisms of the existing facilities, and suggestions for their improvement and extension. On Monday, March 2nd, at 5.30 p.m., Prof. H. MacLean will lecture for the Fellowship in the West Lecture Hall on Renal Disease: Its Diagnosis and Treatment. A three-weeks' course in medicine, surgery, and gynaecology will begin at the Royal Waterloo Hospital on March 2nd. Lectures and demonstrations will be given by the staff in the wards and out-patient department, with special reference to gynaecological diagnosis, hernia, diseases of the stomach, intestines, &c. From March 4th to 28th Dr. Frederic Thomson will hold a series of demonstrations in the Diagnosis and Treatment of the Acute Infectious Diseases at the North-Eastern Fever Hospital (Tottenham). The demonstrations will be given on Wednesdays and Saturdays at 11 a.m. The Central London Ophthalmic Hospital has arranged an afternoon course in ophthalmology, starting from March 9th to April 4th. The members of the staff will deal with the different aspects of diseases of the eye, and for those desiring operative work a class can be arranged. From March 16th to 28th the Chelsea Hospital for Women will begin a fortnight's course in gynaecology. Operations, lectures, and demonstrations will be available. The Brompton Hospital for Diseases of the Chest will conduct a fortnight's course from March 16th, which will include artificial pneumothorax, bronchitis, demonstrations of cases, X ray work, protein tests, and the varying phases of chest affections. The Royal Northern Hospital, in conjunction with the Royal Chest Hospital, will give an intensive course in medicine, surgery, and the special departments from March 16th to April 4th. Copies of the syllabus of the above-mentioned courses, together with the February issue of the Bulletin, will be sent on application to the Secretary of the Fellowship, 1, Wimpole-street, London, W.

Dr. David Alexander Volume has been appointed an official member of the executive council of the Presidency of the Virgin Islands.

WESTON-SUPER-MARE HOSPITAL.—This institution has become so inadequate that an attempt is being made to raise between £40,000 and £50,000 to enlarge or improve it, and in the first 21 days of an intensive campaign over £22,000 was obtained. In the summer the population of Weston swells to 100,000, but the hospital contains only 41 beds, of which 6 are fever beds. In addition to more medical wards, a number of new or improved departments are needed.

INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY. The annual general meeting of this society will take place in Paris this year on April 20th, at Prof. Carnot's Library, Laboratoire de Thérapeutique, Faculté de Médecine (Ecole Pratique), when discussions will be held on (a) the Treatment of Diabetes by Insulin, from the Hydrological Point of View, and (b) the Spa Treatment of Rheumatic Exudations following Traumatism. On the following day visits will be paid to hospitals, the Radium Institute, the Institut d'Hydrologie, and other places of interest. The hon. secretary is Dr. E. P. Poulton, 36, Devonshire-place, London, W. 1, from whom further particulars may be obtained.

GLASGOW WESTERN INFIRMARY.—Like the Glasgow Royal Infirmary, the annual report of which was summarised in our last issue, the Western Infirmary has had a year of exceptional revenue from legacies, the total sum received under that head exceeding £94,000. The ordinary revenue, although increased, failed, however, to meet the ordinary expenditure by nearly £11,000. The infirmary, which has just completed its first half-century, has a daily average of 518 patients. It is hoped to establish a bio-chemical department at a cost of £25,000, towards which a donation of £5,000 has been received. A memorial chapel is approaching completion.

REDLANDS HOSPITAL FOR WOMEN, GLASGOW.—The new home of this hospital, formerly the Glasgow Women's Private Hospital, has been opened by Lady Rhondda. Its special object is the treatment of women by women doctors, the patients whom it is intended to benefit being those who cannot be treated at home or afford to go to a nursing home, and are undesirous of going to a general hospital. The hospital began in 1903 with eight beds; there are now 50. The cost of purchase and equipment has been above £20,000, and the new name is that of a large private residence which has been converted to hospital uses with remarkable success.

THE LATE DR. J. L. OWEN.—John Lewis Owen, M.R.C.S., L.R.C.P. Lond., of Holyhead, Anglesey, died recently in a London nursing home, at the age of 57, following an operation. A native of Anglesey he studied medicine at Edinburgh, where he was a demonstrator of anatomy in Surgeons' Hall. He qualified in 1888. For a time he was resident medical officer at the Union Infirmary, Sheffield, and resident surgeon at Denbighshire Infirmary, before setting up in practice at Holyhead, where he worked for 25 years. For many years he was medical officer of health and public vaccinator to Holyhead Union and Board of Guardians. He was also surgeon to the Admiralty and Trinity Corporation, Holyhead, and also a justice of the peace for his native county. He leaves a widow and a daughter.

MANCHESTER HOSPITALS.—The past year's accounts of the Manchester Royal Infirmary show a deficit of £24,000, the result, to a certain extent, of the abandonment of the custom of placing the whole of the year's legacies to income account—only 25 per cent. has been so dealt with, that the income may be equalised. There has been a remarkable increase in the number of accident patients treated—at over 24,000 they were nearly 6000 more than in 1921. It has been observed that the number of accident cases mounts steadily from January to July, when they began as steadily to decrease. There are 1250 patients on the waiting list. The most urgent need is additional accommodation for the nurses. It is desired so to increase the number that their working hours may be reduced from 63 per week for day and 73 for night-duty to an all-round week of 56 hours. To do this 70 additional nurses would be required.—Manchester Northern Hospital for Women and Children is about to appeal for a building fund of £180,000.—The Manchester and Salford Hospital for Skin diseases also contemplates large extensions. A "Norris Midwood Memorial Wing" is to be built to commemorate the late Mr. Midwood, who was hon. treasurer for nearly 30 years. It is hoped to include a large department for artificial sunlight treatment.

THE LATE DR. A. ROBINSON.—On Feb. 17th Alfred Robinson, M.D. Durh., L.S.Sc., medical officer of health for Rotherham, died after several weeks' illness. He was born in 1860 at Merthyr Tydfil and studied medicine at St. Bartholomew's Hospital and the University of Durham, and graduated M.B. Durh. in 1883 and M.D. in 1887, having previously qualified M.R.C.S. in 1882, and L.S.A. in 1881. He went to Rotherham in 1884, where his first medical appointment was that of medical officer to the Rotherham Workhouse, which he resigned after 21 years' service. He was appointed borough medical officer and police surgeon in 1892. He was at one time president of the Sheffield Medico-Chirurgical Society and also of the Yorkshire Branch of the Society of Medical Officers of Health. For many years he was connected with the Volunteer movement, and did service during the war, retiring as Major of R.A.M.C. He inaugurated the Child Welfare Centre in Rotherham and also a maternity home, and was chiefly responsible for the establishment of an isolation hospital, a small-pox hospital, and subsequently a sanatorium.

ADULTERATION OF FOOD IN SALFORD.—Mr. G. D. Elsdon, the borough analyst of Salford, in his annual report shows that in certain foods in common use there is adulteration on a rather extensive scale. Of the 1388 samples taken under the Sale of Food and Drugs Act, 6.9 were returned as adulterated, as compared with 5.6 per cent. of the samples in 1922, and 8.7 in 1921. In a sample of "Beef and Malt Wine" the mixture was made up of over 75 per cent. of water, nearly 22 of sugar, and 0.2 per cent. of equal parts of meat and malt extracts. The amount of alcohol was 1.5 per cent. and salicylic acid 0.07 per cent. Of 104 samples of drugs, only three were found adulterated. Of 56 samples of dispensed medicines made up from "prescriptions," six were returned as unsatisfactory.

THE LATE DR. FRANK W. A. GODFREY.—By the recent death of Frank William Albion Godfrey, M.B., C.M. Edin., of Scarborough, at the age of 64, in a Leeds nursing home, following complications arising from an attack of influenza, Scarborough has lost one of its best-known practitioners. Frank Godfrey was born at sea while his parents were on a passage to Australia. He received his early education in Australia and studied medicine at the University of Edinburgh, where, in 1883, he graduated with honours. After holding hospital appointments in Edinburgh and Scarborough, he became assistant to the late Dr. Hartley, of Malton, whose daughter he married. He finally settled in Scarborough, where later he became an honorary consulting surgeon to the hospital and dispensary. He was a county magistrate and J.P. for Scarborough, a member of the Leeds and West Riding Medico-Chirurgical Society, a former president of the York Medical Society, and, in 1909, president of the Yorks Branch of the British Medical Association. He was one of the founders of the Ganton Golf Club and a Past-Master of the Old Globe Lodge of Freemasons. Dr. Godfrey is survived by Mrs. Godfrey and three daughters.

POOR-LAW UNIONS AND VOLUNTARY HOSPITALS.—In his address to the 50th Central Conference of the Poor-law Guardians of England and Wales the Chairman, the Rev. Lancelot R. Phelps, Provost of Oriel, said that the voluntary hospitals were so hard put to it that the guardians must come to their aid. There was here a field of constructive adventure, and if the guardians could fill it they would do much to increase the efficiency of labour by shortening the time of sickness. This could best be accomplished by specialisation and getting rid of the old idea of the mixed workhouse, by reckoning up the needs of a district, converting some of the workhouses into hospitals pure and simple, and making provision for other classes of inmates. The provision for the sick within a district formed by several unions should be under the care of a joint committee representing the Unions and the voluntary hospitals.

A BIRMINGHAM AMALGAMATION.—A scheme for the amalgamation of the Royal Orthopaedic and Spinal Hospital and the Birmingham Cripples' Union has been approved by the General Committee of both hospitals. The Orthopaedic Hospital, which was established in 1817, has long been in need of extension; the Cripples' Union dates from 1896. The scheme is based upon the complete pooling of all buildings, equipment, and financial resources, and a union of staffs. Arrangements for a considerable increase in the number of hospital beds for the treatment of cripples of all ages are under consideration. The Cripples' Union, with 180 beds, is the third largest hospital charity in Birmingham, and the Orthopaedic Hospital has recently received from its chairman, Mr. J. H. Francis, a gift of leasehold premises at Edgbaston which will accommodate 30 convalescents. It is hoped that the amalgamation will enable adequate provision to be made for Birmingham and the

surrounding areas, by the aid of local clinics in Coventry, the Black Country towns, &c., and the organisation of a system of after-care such as is already in operation in the city in connexion with the Cripples' Union. During the past 12 months the combined expenditure of the two institutions exceeded £40,000.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The eighteenth meeting of this Commission was held at the Home Office, Whitehall, on Feb. 19th, Lord Lawrence of Kingsgate in the chair. The British Lental Association, represented by Dr. John H. Badcock, L.D.S., Mr. Ernest Y. Richardson, L.D.S., and Mr. Bryan J. Wood, L.D.S., gave evidence on the question of making dental treatment a universal benefit under the Health Insurance Act, and the scope, administration, and cost of such a benefit. The British Society of Dental Surgeons, represented by Sir Frank Colyer and Dr. E. W. Fish, gave evidence on the same range of subjects. Thereafter Mr. R. J. Meller, M.P., and Mr. E. F. Spurgeon, representing the Prudential Approved Societies, were examined on a variety of matters relating to the administration of the society. The Commissioner announced that proof copies of the oral evidence and the relative statements submitted at the meeting of Feb. 5th are now on sale at His Majesty's Stationery Office. (2s. 3d.)

MINERS' WELFARE SCHEME.—The levy of a penny per ton on all coal raised in Great Britain for the Miners' Welfare Scheme is to be continued for another five years, both coalowners and miners being unanimous that it should be continued. The joint committee of owners and men will thus be able to prolong one of the largest and most valuable experiments in industrial welfare that this country has produced. The funds already allocated or in hand amount to nearly £3,000,000. One-fifth of the levy goes to a general fund and is expended on mining education and research into problems of health and safety. By grants from the fund pithead baths, recreation grounds, clubs, and institutes have been established, and convalescent homes for miners endowed. Such a scheme might well be adopted by other great industries.

HARROGATE INFIRMARY.—The supporters of this hospital have at last, thanks to the honorary medical staff, found a way out of the difficulties caused by the proposed enlargement. Two schemes had been proposed—the extension of the existing building, and the erection of a modern hospital on a new site. The first was roundly condemned by the 16 members of the honorary staff as "bad from all points of view"—an opinion confirmed by the experts who were consulted by the Building Committee; finance was felt to be an insuperable obstacle to the second. Thereupon the honorary staff proposed a plan of their own. They suggested the purchase of a site of six or eight acres and the building upon it of a medical department of 40 beds, with a kitchen adequate for 120 beds. It was claimed that the wards of the present infirmary would thus be relieved of medical cases, and that more room would be found for surgical cases without the need for alterations. The urgent need of additional accommodation would thus be met, and the nucleus formed of a modern hospital, to be completed as money becomes available. At the annual meeting of subscribers the scheme, which will cost £40,000, was opposed. The present accommodation of the infirmary is 60 beds.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 14TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 150; scarlet fever, 1653; diphtheria, 1045; enteric fever, 42; pneumonia, 1742; puerperal fever, 36; cerebro-spinal fever, 9; acute poliomyelitis, 6; encephalitis lethargica, 51; dysentery, 9; ophthalmia neonatorum, 119. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases showed an increase of 12 over the number for the preceding week. Twenty-nine cases were notified from Derbyshire, 6 from Lincolnshire (Sleaford, 6), 16 from Northumberland, 22 from Notts, and 61 from Yorks, North Riding, (Middlesbrough, C.B. 57).

Deaths.—In the aggregate of great towns, including London, there were 6 deaths from enteric fever, 65 from measles, 11 from scarlet fever, 133 from whooping-cough 41 from diphtheria, and 354 from influenza, as compared with 291, 202, 195, and 142 in the four preceding weeks. In London itself the deaths from influenza numbered 92, from whooping-cough 47, and from diphtheria 11.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, March 2nd.

TROPICAL DISEASES AND PARASITOLOGY: Special Meeting at 5.30 P.M.

Paper:

Dr. Henry E. Meleney (Union Medical College, Peking): Kala-azar in China: with Special Reference to its Histo-pathology in Experimentally Infected Hamsters. Histological sections will be shown, and lantern slides illustrating some of the special features of the infections.

EPIDEMIOLOGY

COMPARATIVE MEDICINE

DISEASE IN CHILDREN

Special Discussion: at 8 P.M.
The Control of Tuberculosis and the Milk-supply (adjourned from Feb. 9th).

Speakers:

Dr. M. J. Rowlands, Dr. Stenhouse Williams, Dr. David Nabarro, Sir Layton Blenkinsop, Dr. Nathan Raw, Mr. G. P. Male, Sir Henry Gauvain, Dr. A. Stanley Griffiths, and others.

Tuesday, March 3rd.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.).

Cases will be shown by Mr. Jenner Verrall and others.

PATHOLOGY: at 8 for 8.30 P.M. at the Lister Institute, Chelsea, S.W.

Demonstrations:

T. Lumsden: The Effects of an Anti-serum on Cancer Cells in vitro.

H. Schutze and S. S. Zilva: Experimental Tubercle in Rats.

Communications:

V. Korenchevsky: Some Important Points in the Technique Necessary for the Accurate Study of Metabolism in Rabbits.

B. Korenchevsky and M. Carr: Studies in the Internal Secretion of Sexual Glands: Influence of the Testis and Prostate on the Nitrogen Metabolism of Rabbits.

R. St. J. Brooks: The Serological and Biochemical Reactions of Pathogenic Plant Bacteria.

J. C. G. Ledingham: The Guarneri Body.

S. P. Bedson, H. B. Maitland, and M. Burbury: Foot-and-Mouth Disease in the Guinea-pig.

Wednesday, March 4th.

BALNEOLOGY AND CLIMATOLOGY

EPIDEMIOLOGY AND STATE MEDICINE

MEDICINE

THERAPEUTICS AND PHARMACOLOGY.

Special Discussion: at 5.30 P.M.
The Nature, Prevention and Treatment of Fibrositis.

Dr. W. Edgecombe will open the Discussion for the Section of Balneology, followed by Dr. J. A. Glover (Epidemiology), Sir William Willcox (Medicine), and Dr. P. Hanuli (Therapeutics).

Other Speakers:

Dr. Ackerley, Dr. Midelton, Dr. Kerr Pringle, Sir Percy Bassett-Smith, Dr. R. Hill, Mr. J. E. R. McDonagh, Dr. M. B. Ray, Dr. Oliver Heath, Dr. C. E. Sundell, and Dr. Higgins.

(The Discussion will be continued on Thursday, March 5th, at 5.30 P.M.)

SURGERY: at 8.30 P.M.

Communication:

Mr. Pinthu Sai (Bangkok): A Case of Sarcoma of the Breast

Discussion on

The Mortality of Appendicitis, to be opened by Mr. Joseph Adams and Mr. McNeill Lowe.

Thursday, March 5th.

BALNEOLOGY AND CLIMATOLOGY

EPIDEMIOLOGY AND STATE MEDICINE

MEDICINE

THERAPEUTICS AND PHARMACOLOGY

Special Discussion: at 5.30 P.M.
The Nature, Prevention and Treatment of Fibrositis.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.

Specimens:

Mr. Beckwith Whitehouse: (1) Uterus and Vagina Excised for Epithelioma of Vagina. (2) Sarcoma Botryoides of Cervix Uteri. (3) Mesenteric Dermoid.

Prof. Louise McIlroy: Retroplacental Hematoma from a Case of Toxæmia of Pregnancy.

Short Communications:

Dr. J. S. Fairbairn and Dr. Z. Mennell: Toxæmia in Early Pregnancy with Jaundice, Hyperemesis and Multiple Neuritis.

Mr. Everard Williams and Dr. Russell Reynolds: A New Method of Determining the Patency of the Fallopian Tubes by Means of X Rays.

Paper:

Dr. Sidney Forsdike: Investigation of the Uterus and Fallopian Tube by Inflation with Air and X Rays.

Friday, March 6th.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)

Cases and Specimens will be shown.

ANÆSTHETICS: at 8.30 P.M.

Paper:

Mr. F. S. Rood: Extradural Anaesthesia.

Saturday, March 7th.

OTOLOGY: at 10.30 A.M. (Cases at 9.45 A.M.)

Cases and Specimens will be shown.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

WEDNESDAY, March 4th.—9 P.M., Sir Bernard Spilsbury: Wounds and Other Injuries in Their Medico-Legal Aspect (Second Lettsomian Lecture).

HUNTERIAN SOCIETY.

MONDAY, March 2nd.—9 P.M. (at the London Mansion House).—Dr. H. L. Tidy: Anglo-Hæmic Anæmia. (Hunterian Oration.)

LECTURES, ADDRESSES, DEMONSTRATIONS &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, March 2nd to SATURDAY, March 7th, 1925.—

WEST LECTURE HALL, Royal Society of Medicine, 1, Wimpole-street, W. Lecture arranged by the Fellowship of Medicine and open to all members of the medical profession. Monday, March 2nd, at 5.30 P.M., Prof. H. MacLean on Renal Disease—Its Diagnosis and Treatment.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynecology. Lecture-Demonstrations will be given in the Wards and Out-patient Departments.—NORTH-EASTERN FEVER HOSPITAL, St. Anne's-road, Tottenham, N. Wednesday and Saturday, at 11 A.M., Demonstrations on the Diagnosis and Treatment of the Acute Infectious Diseases will be given by Dr. Frederic Thomson.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C.1.

POST-GRADUATE COURSE: FEB.—MARCH, 1925.

CLINICAL LECTURES AND DEMONSTRATIONS.

MONDAY, March 2nd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Chorea: Dr. Kinnier Wilson.

TUESDAY, March 3rd.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Pathology of Cerebral Tumours: Dr. J. G. Greenfield.

THURSDAY, March 5th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Radiology in the Diagnosis and Treatment of Nervous Diseases: Dr. Russell Reynolds.

FRIDAY, March 6th.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Surgical Treatment of Spastic Conditions: Mr. Percy Sargent.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.

THURSDAY, March 5th.—12 noon, The Neuron: Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

MONDAY, March 2nd.—12 noon, Cerebellum: Dr. Hinds Howell.

The Fee for this Course will be £2 2s.

Dr. H. J. MacBride will give a COURSE OF EIGHT CLINICAL DEMONSTRATIONS, chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM, in the Wards at 10 A.M. on Tuesdays and Fridays, if sufficient entries are received. The Fee for this Course will be £2 2s.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE NEUROLOGY OF THE EYES.

WEDNESDAY, March 4th.—3.30 P.M., The Oculomotor Nerves: Mr. Leslie Paton.

Applications for this Course should be made early. Fee £5 5s. if taken as a separate Course, or £3 3s. if taken with the General Course.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course. J. G. GREENFIELD, Dean of Medical School.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

TUESDAY, March 3rd.—4.30 P.M., Dr. J. Browning Alexander: Modern Views on the Treatment of Diabetes.

FRIDAY.—4.30 P.M., Mr. W. Ibbotson: Nasal Catarrh: A General Discussion.

Daily, In-patient and Out-patient Cliniques, Operations, Cliniques in Special Departments, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 5th.—4 P.M., Dr. Still: Some Hæmorrhagic Affections in Childhood.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL POST-GRADUATE LECTURES, Marylebone-road, N.W.

THURSDAY, March 5th.—5 P.M., Mr. L. G. Phillips: Some Common Obstetric Difficulties.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

TUESDAY, March 3rd.—5 P.M., Dr. Wilfrid Fox: Nævi.

THURSDAY.—5 P.M., Dr. H. G. Adamson: Benign Growths of the Skin.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, March 2nd.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.

2 P.M., Dr. Scott Pinchin: Medical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—11 A.M., Medical Registrar: Medical Wards. 12.15 P.M., Dr. Burnford: Medical Pathology. 2 P.M., Dr. Owen: Medical Out-patients.

THURSDAY.—11 A.M., Sir Henry Simson: Gynecological Wards. 12 noon, Mr. Sinclair: Abdominal Surgery (Lecture). 2 P.M., Mr. Bishop Harman: Eye Dept.

FRIDAY.—10.30 A.M., Dr. Dowling: Skin Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—9.30 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children.

10 A.M., Mr. Banks-Davis: Operations on Throat, Nose and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION, 11, Chandos-street, Cavendish-square, W.

FRIDAY, March 6th.—4.30 P.M., Dr. E. W. Goodall and Dr. G. E. Friend: A Discussion on the Differential Diagnosis of Scarlet Fever, Rubella, and Measles and Allied Rashes.

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)

MONDAY, March 2nd.—(At the Children's Hospital.) Mr. Morrison: Surgical Diseases of the Kidneys in Childhood.

TUESDAY.—(At the Southern Hospital.) Mr. W. R. Williams: The Treatment of Whitlows.

WEDNESDAY.—(At the Northern Hospital.) Dr. Pemberton: Subinfections.

THURSDAY.—(At the Stanley Hospital.) Miss R. Nicholson: Ovarian Tumours.

MANCHESTER MEDICAL SOCIETY.

THURSDAY, March 5th.—4 P.M., Joint Meeting with the Liverpool Medical Institution, at Liverpool. Prof. A. Ramsbottom: Dizzy Attacks. Mr. J. B. Macalpine: Vesical Papilloma. Dr. H. Platt: Considerations on Loose Bodies in Joints.

ANCOATS HOSPITAL.

THURSDAY, March 5th.—4.30 P.M., Dr. Norman Kletz: Dyspepsia.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, March 3rd.—4.15 P.M., Dr. T. H. Oliver: Practical Points in Diabetes.

ST. MARY'S HOSPITALS, MANCHESTER, POST-GRADUATE LECTURE (at Whitworth-street West Branch).

FRIDAY, March 6th.—4.30 P.M., Dr. D. Dougal: Displacements of the Uterus in Relation to Pregnancy and Labour.

ST. ANDREWS INSTITUTE FOR CLINICAL RESEARCH

TUESDAY, March 3rd.—4 P.M., Dr. C. E. Douglas: Albuminuria and Pregnancy. Discussion.

THE PEOPLE'S LEAGUE OF HEALTH.

Lectures on What We Should Eat and Why, at the Medical Society of London, 11, Chandos-street, W.

TUESDAY, March 3rd.—6 P.M., Prof. R. H. A. Plimmer: Common Errors in Diet.

Appointments.

BYRD, C. B., L.R.C.P. Lond., M.R.C.S., has been appointed

Certifying Surgeon under the Factory and Workshop Acts for the Patterdale District of the County of Westmorland.

SHAW, WILLIAM FLETCHER, M.D. Manch., appointed to the Chair of Obstetrics and Gynecology in the University of Manchester.

Cheltenham General Hospital: LIDDERDALE, F. J., M.B., B.S. Durh., D.P.H., Hon. Physician; DAVEY, J. B., M.B., M.R.C.S., L.R.C.P., D.T.M., Hon. Pathologist.

St. Paul's Hospital for Skin and Genito-Urinary Diseases: WALKER, KENNETH, F.R.C.S. Eng., Honorary Surgeon; EVANS, Sir THOMAS J. CAREY, F.R.C.S. Eng., and WINSBURY WHITE, H. P., F.R.C.S. Eng., Honorary Assistant Surgeons.

Vacancies.

For further information refer to the advertisement columns.

Barnet, Wellhouse Hospital.—Asst. R.M.O. £150.

British Hospital for Mental Disorders, &c., 72, Camden-road, N.W.—Hon. P.

Cambridge, Addenbrooke's Hospital.—H.S. at rate of £130.

Cardiff, Welsh National School of Medicine.—Asst. Lecturer in Dept. of Physiology. £400.

Derbyshire County Council.—M.O.H., &c. £1400.

Ealing Borough.—Asst. M.O.H. £600.

Federated Malay States.—Research Studentship in Tropical Medicine. £700.

Grimsby, County Borough Education Committee.—Den'tal S. £300.

Hospital for Sick Children, Great Ormond-street, W.C.—Surg. Reg. £300.
Inverness, Northern Infirmary.—Jun. M.O. £100.
King's College Hospital, Denmark Hill, S.E.—Jun. Obstet. and Gynaecol. S.
Liverpool Open-air Hospital for Children, Leasowe, for Non-Pulmonary Tuberculosis.—Jun. M.O. £200.
London Temperance Hospital, Hampstead-road, N.W.—Dermatologist.
Manchester, Ancoats Hospital.—Res. M.O. and Pathological Reg. at rate of £175 and £100 respectively.
Manchester, Christie Hospital.—Cancer Research Worker. £500.
Manchester, Hulme Dispensary, Dale-street.—Hon. S.
Manchester, Salford Royal Hospital.—H.S. and Cas. H.S. Each at rate of £125.
Metropolitan Asylums Board, Infectious Hospitals Service.—Asst. M.O.'s. £500.
Metropolitan Hospital, Kingsland-road, E.—Hon. Anaesthetist.
National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—Asst. Ophth. S.
Nottingham General Hospital.—Pathologist. £350 and private fees allowed.
Oldham Royal Infirmary.—H.S. a rate of £200.
Prince of Wales's General Hospital, Tottenham, N.—Hon. Anaesthetist. £20.
Royal Chest Hospital, City-road, E.C.—Phys. Also Hon. Radiologist.
Royal Dental Hospital of London, Leicester-square, W.C.—Asst. Dent. S.
Royal Northern Hospital, Holloway, N.—M.O. to Out-patient Dept. at rate of £125. H.S. at rate of £75. Also Asst. Radiologist. £150.
St. Mary's Hospital Institute of Pathology and Research, Paddington, W.—Research Studentship at rate of £200.
St. Pancras Metropolitan Borough.—M.O.'s Infant Consultations. 1½ guineas per consultation.
St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—H.S. at rate of £75.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—S. to In-patients and S. to Out-patients.
Sheffield Royal Hospital.—Hon. Radiologist.
Southampton County Borough.—Asst. M.O.H. £600.
Stockport County Borough.—Asst. Med. Off. Health. £600.
Sudan Medical Service.—Two Med. Inspectors. £E.720.
Sutton, Surrey, The Downs Hospital for Children.—Jun. Asst. M.O. £500.
University College Hospital, Gower-street, W.C.—Obstet. Phys.
West London Hospital, Hammersmith-road, W.—H.P. and 2 H.S.'s. Each at rate of £100.
West Riding County Council.—Dist. Tuberculosis O. £600.
Wilkesden General Hospital, Harlesden-road, N.W.—Temp. Asst. Hon. Radiologist.

Births, Marriages, and Deaths.

BIRTHS.

CREASY.—On Feb. 17th, at Devonshire-place, W., the wife of Dr. Rolf Creasy, junr., of a daughter.
 GRANT.—On Feb. 11th, at Sidney House, Shrewsbury, the wife of W. J. Grant, M.D., F.R.C.S., of a son.
 MACDONNELL.—On Feb. 19th, at 89, Lower Baggot-street, Dublin (Nursing Home), the wife of J. J. MacDonnell, M.B., of a daughter.
 MATTHEW.—On Feb. 15th, at Redgarth, Dundee, the wife of Dr. David Matthew, of a son.

MARRIAGES.

LOCK—PUNNETT.—On Feb. 18th, at Holy Trinity Church, Tunbridge Wells, Percy Gonville Lock, M.A. Camb., M.R.C.S., L.R.C.P., to Clare, widow of Edward John Punnett, of Tonbridge.
 READER—HARMER.—On Feb. 14th, at Bickley, Kent, N. L. M. Reader, M.S., F.R.C.S., to Mabel Kathleen, daughter of Mr. and Mrs. P. J. Harmer, of Cotswold, Bickley, Kent.

DEATHS.

ALLBUTT.—On Feb. 22nd, suddenly, at S. Radegund's, Cambridge, the Rt. Hon. Sir Thomas Clifford Allbutt, K.C.B., M.D., Regius Professor of Physic in the University of Cambridge, in his 89th year.
 CUTHBERTSON.—On Feb. 15th, at Bexley, Captain John Oswald Cuthbertson, R.A.M.C., M.B., B.A., in his 54th year.
 HACKETT.—On Feb. 15th, at Ocala, Eldorado-road, Cheltenham, Colonel R. I. D. Hackett, C.B.E., M.A., M.D., late Army Medical Service.
 MARTIN.—On Feb. 19th, at "Strangford," Church-road, Ashford, Kent, Albert Edmund Samuel Martin, F.R.C.S. (Ireland), aged 41.
 MORRELL.—On Feb. 19th, suddenly, at Sheffield, Reginald Arthur Morrell, M.R.C.S., aged 39.
 SIMONS.—On Feb. 15th, at Bath, Lieut.-Colonel Robert J. Simons, R.A.M.C., of Corsham, Wilts., in his 59th year.
 N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

GERMAN HOSPITAL, DALSTON.—The annual report shows that the number of in-patients treated last year was 1971, including 200 accident cases, nearly all of which were English. The system of patients' contributions has become a stabilising financial factor, and is expected normally to produce between £7000 and £8000 a year.

Parliamentary Intelligence.

HOUSE OF COMMONS.

TUESDAY, FEB. 17TH.

Silicosis and Workmen's Compensation.

Mr. CECIL WILSON asked the Home Secretary whether, in view of the serious effect of silicosis on the curtailment of life in persons engaged in grinding trades, he could see his way to the introduction of a Bill amending the Workmen's Compensation (Silicosis) Act, 1918, so as to cover disablement due to silicosis or silicosis accompanied by tuberculosis in the grinding trades.—Sir WILLIAM JOYNSON-HICKS replied: The Act of 1918 empowers the Secretary of State to make a scheme for the payment of compensation in any industry or group of industries involving exposure to silica dust. No further legislation therefore is necessary. The question of a scheme for the grinding trades has been referred for advice to the Departmental Committee on Compensation for Silicosis, and further action must depend on the Committee's report.

Labelling of Manufactured Foods.

Sir WILFRID SUGDEN asked the Minister of Health if he would give facilities for the introduction of legislation requiring manufactured food to be labelled with full details of its contents and ingredients.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied: Any legislation which may be introduced on these lines would have my right hon. friend's careful consideration, but he is afraid it is not likely that any special facilities could be given in this connexion.

Increase in Population.

Mr. HERBERT WILLIAMS asked the Minister of Health if he would state the total estimated increase in population from the armistice up to December, 1924; the total number of houses completed in that period; and the number demolished during the same period.—Sir KINGSLEY WOOD replied: The total estimated increase in the population of England and Wales from the armistice up to December, 1924, is 1,402,000. In connexion with State-assisted schemes 263,396 houses have been completed during this period. Complete information as the number of houses erected without State assistance is not available, but during the two years for which figures are available—viz., to Sept. 30th last—some 126,000 houses were built by private enterprise without State aid. My right hon. friend has no information as to the total number of houses demolished during the period, but according to reports of medical officers of health for the year 1920 to 1923 inclusive action by local authorities under Section 18 of the Housing, Town Planning, &c., Act, 1909, resulted in the demolition of 2568 houses.

WEDNESDAY, FEB. 18TH.

Industrial Accidents in 1924.

Lord HENRY CAVENDISH-BENTINCK asked the Home Secretary the total number of industrial accidents for 1924; and the number of fatal industrial accidents for the same period.—Sir W. JOYNSON-HICKS replied: The total number of accidents reported under the Factory and Workshops Acts in 1924 was 169,726, of which 953 were fatal. These figures are provisional only and may be subject to slight correction. I regret that I am unable to give the figures of accidents in industries not covered by the Factory Acts.

Mentally and Physically Defective School Children.

Colonel DAY asked the President of the Board of Education what was the number of mentally deficient and the number of physically defective children in public elementary schools and the number in each group for whom provision was made in special schools.—Lord E. PERCY replied: According to the returns from local education authorities for 1923, it would appear that there are, in England and Wales, about 30,000 educable mentally defective children and about 106,000 physically defective children, among whom are included about 49,000 classed as "delicate," and that of these children about 11,000 mentally defective and about 67,000 physically defective children (including about 36,500 children classed as "delicate") are attending public elementary schools. At the present time there is accommodation in special schools for 16,565 mentally defective children and for 16,608 physically defective children. For full details I would refer the hon. and gallant member to Section VI. of the report of the Board's chief medical officer for 1923.

Demolition of Slum and Insanitary Areas.

Captain GARRO-JONES asked the Minister of Health whether he was aware that the chief obstacle to the demolition of slum and insanitary areas was now the lack of alternative

accommodation; and whether he would cause a survey of such possible accommodation to be commenced at once and give instructions that the survey should encompass not only vacant houses of all types, but also houses used as workshops and unoccupied institutions, as, for example, the casual ward of the Hackney Union.—Mr. NEVILLE CHAMBERLAIN replied: Schemes for the clearance of insanitary areas provide for the building of alternative accommodation for the re-housing of the occupants who will be displaced. Local authorities have power to acquire and adapt existing property, but the adaptation of existing buildings has usually been found to be costly and unsatisfactory, and I do not think that the advantages of a survey, such as is suggested, would be commensurate with the cost of making it.

Vaccination Exemptions in 1923.

Mr. SAVERY asked the Minister of Health the number of children on behalf of whom exemption from vaccination was claimed during the year 1924; and how many of those claims were allowed.—Mr. NEVILLE CHAMBERLAIN replied: The last year for which particulars are at present available is 1923. During that year statutory declarations of conscientious objections to vaccination were received by vaccination officers in respect of 284,551 children. I have no information as to the number, if any, of statutory declarations which were not accepted because they did not comply with the statute or were otherwise invalid.

Tuberculosis Order, 1914.

Sir FRANCIS WATSON asked the Minister of Agriculture whether it was intended to reintroduce the Tuberculosis Order of 1914 with regard to cattle, which sought to eliminate certain classes of diseased animals from a herd.—Mr. WOOD replied: This matter is now under the consideration of the Government and I hope to be in a position to make a statement at an early date.

Public Health Acts Amendment Bill.

Mr. ROBERT WILSON asked the Minister of Health if he proposed to introduce a Public Health Acts Amendment Bill on the lines of the Amendment Acts of 1890 and 1907, embodying provisions which had been passed in private Acts by the Local Legislation Committee of the House of Commons.—Mr. NEVILLE CHAMBERLAIN replied: I hope to be able to introduce such a Bill, but I cannot say whether it will be possible to introduce it this session.

Poor-law Medical Officers' Salaries.

Mr. WARNE asked the Minister of Health the number of Poor-law medical officers and the cost of salaries per annum; and the number of deaths in workhouses and the bodies removed for medical and dissection purposes in the years 1914 and 1923.—Mr. NEVILLE CHAMBERLAIN replied: Information giving the number of Poor-law medical officers is not available, nor is separate information as to their salaries. The approximate total remuneration of Poor-law medical officers, dispensers, and nurses in the year 1922-23 was £1,900,000. 59,524 deaths occurred in Poor-law institutions in 1914, 60,911 such deaths in 1923. The number of bodies removed to medical schools in England and Wales for the purpose of anatomical examination and operative surgery was in 1914, 301, and in 1923, 388.

Assistance to Crippled Children.

Sir CHARLES CAYZER asked the Minister of Health what provision, if any, was made by the State for assistance in any way to crippled children.—Mr. NEVILLE CHAMBERLAIN replied: Grants are available from the Exchequer towards expenditure incurred by local authorities for the treatment and after-care of crippled children in accordance with arrangements approved by the responsible department of State, which may be either the Board of Education or the Ministry of Health.

TUESDAY, FEB. 24TH.

Royal Commission on National Insurance.

Mr. HAYDAY asked the Prime Minister whether he was prepared to recommend the extension of the terms of reference of the Royal Commission on National Health Insurance.—Mr. BALDWIN replied: No Sir, it is not proposed to extend the terms of reference of a commission constituted to deal with the particular question of National Health Insurance.

CHILD WELFARE.—The annual general meeting of the National League for Health, Maternity and Child Welfare, and of the National Association for the Prevention of Infant Mortality will be held at Carnegie House, 117, Piccadilly, London, W.1, to-day (Friday), Feb. 27th, at 3 P.M., when Lieut.-Colonel F. E. Fremantle, M.P., will give an address on Parliament and the Public Health. Dr. Amand Routh will be in the chair.

Notes, Comments, and Abstracts.

NUTRITION.

By J. V. A. SIMPSON, M.D. LOND., D.P.H. CAMB.,
DEPUTY MEDICAL OFFICER OF HEALTH AND SCHOOL
MEDICAL OFFICER, TORQUAY.

IN attempting to outline what is meant by the term "nutrition" it is at once seen that there is great difficulty of exact statement, for nutrition is a complex process. With reference to the use of the Dunfermline scale, Dr. Alister Mackenzie wrote that in judging and classifying nutrition "the general appearance of the child, the condition of the skin and subcutaneous tissues, the muscular tone and development, the state of the mucous membranes, the vigour or listlessness which may appear in the child's facial expression, carriage, movements, voice, interest, all contribute to our decision."¹ And Sir George Newman said: "Sound nutrition is a general physiological condition which connotes a healthy body in all respects and the good tone and health of its various constituent parts In regard to diagnosis, therefore, the school medical officer has as yet neither an absolute standard of nutrition nor a single criterion to guide him. He must form a considered and careful opinion on all the facts before him."²

Nevertheless doctors differ, and the personal element must necessarily be a powerful influence in much of the practice of medicine. In certain laboratory tests, in face of definite clinical physical signs, there can be little dispute over the findings and the interpretation of the results, but on such a question as nutrition a variety of conflicting opinions are frequently obtained, even from expert clinicians. Therefore the search for a practical yet simple index of physical fitness has been given much emphasis during the last few years; and progress has taken place mainly along three lines. In the first case the idea of using the Dunfermline scale has been adopted; in this the child is placed in one of four groups: (1) "Excellent" means the nutrition of a healthy child of good social standing; (2) children whose nutrition just falls short of standard 1 are in this group; (3) children "requiring supervision" and are on the borderline of serious impairment constitute this group; (4) children "requiring medical treatment" are those whose nutrition is seriously impaired. This has many advantages, one of which is that whereas the usual "good," "fair," "poor" headings may cause the inspector to place all doubtful cases in the middle group, a fourfold division calls for more thought and generally receives it. Although no considerable progress has been made in developing a scale along these lines, the possibilities have probably not yet been fully explored.

The second method consisted in the use of a single physical characteristic as a measure of fitness, that almost exclusively used being weight; and in employing this criterion, it is essential that a certain amount of deviation from the average be allowed, because this actually occurs among healthy individuals. The limits of this "zone" are not easily made and appear to have been based upon opinion rather than upon investigation, and it has certainly been demonstrated quite clearly "that even for healthy children the variability in weight differs in a marked degree according to sex and age, and it would appear necessary to delimit normal variations for each sex, age, and other groups."³ The third method is to employ variations in more than one physical characteristic, such as weight, sitting height, chest circumference, and vital (lung) capacity; of these the most elaborate is that of Dreyer,⁴ and the possible advances in this direction would appear to be numerous. This method and that of Flack are extremely valuable, and in the annual report (1923) of the school medical officer, Manchester, there is a section dealing with important results in secondary school boys with modifications of these methods. Of other methods the "Pedihsis" factor⁵ of Pirquet has been used, and the standard of Wood⁶ has received wide application in America, where his table has been employed in routine school work.

Excluding the more detailed methods, for these perhaps are not always easily applicable to very young children, the results of several investigations into the reliability of the indices are now available; primarily it would appear that there is no simple gauge of nutrition.^{7 8 9} Failing a complete physical examination, however, all the children who are 7 per cent. underweight for height, age, and sex may be regarded as undernourished.¹⁰ Although such standards cannot diagnose disease, and are only to be subsidiary to complete clinical examination, yet it has been shown that this method seems worthy of use; even if no complete clinical picture of the child's physical condition is given by it, yet "the relation of weight to height and age is the best single index of general health and nutrition

as well as the best criterion of normal growth that we possess."¹¹

The Results of Tests in an Open-air School.

With this in view, and bearing in mind the fact that no measurements other than weight and height were available, it was decided to test the Baldwin-Wood tables and a standard in connexion with the children in the open-air school at Torquay. This investigation involves the records of 148 children extending over a period of about 4½ years; and as the annual reports of the Board of Education recommend six months as a minimum period of stay at an open-air school, any children who were at this school for a less period have been excluded from this survey. Of the 148, about a third are still at the school, but these are included because they have been there for more than six months. The findings should show how far this standard judges malnourished children, for the majority were admitted for malnutrition, anæmia, or allied condition; further, it should be possible to test the results of the school itself, for the application of the same standard to the children as they enter and as they leave the school is a method freed from personal bias. Thus the ratio of cases classed as malnourished before and after treatment at this school will have a significance, the value of which must be admitted as quite definite. In addition, it is possible to find out from these tables the average annual increase of growth for age, sex, and height, and consequently the expected increase can be compared with that actually obtained; this is most valuable, for of greater importance than the weight or height at any given age is the annual increment of growth.

Applying the Baldwin-Wood method to the 148 children, and counting as malnourished all below 7 per cent. of the standard weight for age, sex, and height, results were obtained as shown in Table I.:-

TABLE I.

—	On entering the school.			On leaving the school.		
	Normal	Mal-nourished.	Per-centage mal-nourished.	Normal	Mal-nourished.	Per-centage mal-nourished.
Boys ..	40	37	48.0	64	12	15.6
Girls ..	26	45	63.8	52	20	28.6
Total ..	66	82	55.4	116	32	21.6

The average time spent at the school is given in Table II.:-

TABLE II.

—	Normal.	Malnourished becoming normal.	Malnourished remaining malnourished.
Boys ..	1.6 years	1.8 years	2.2 years
Girls ..	1.7 ..	1.7 ..	1.6 ..

From this it is seen that there is a greater percentage of girls than boys malnourished, in spite of the fact that usually there are slightly more boys than girls at the school. Whether or not this is a mere chance selection it is scarcely possible to say. If it is not, then, although the medical officer drafts more boys than girls to the school, this standard would judge a greater proportion of girls as suffering from malnutrition; this might possibly be due to the greater height of girls at some ages. Approximately just over half the children admitted are below this standard; and it is difficult to say if this standard of malnutrition is correct, for while the majority are admitted for debility, malnutrition, anæmia, and allied conditions, yet a number (in this series approximately 15 per cent.) were admitted as contacts of tuberculous cases, or as children with heart disease, chorea, old infantile paralysis—conditions which would not clinically be called malnourished. The children have been admitted during the four years by no less than three different medical officers, which should equalise the personal factor of selection, and so it would appear that this standard just fails to class as malnourished a definite percentage (in this series about 30 per cent.) of the children. This agrees partly with the American findings,⁹ although there it was found that many more children clinically suffering from malnutrition are missed—it was thought that about two-thirds of the malnourished escape with this standard.

As judging the work of the open-air school the standard is distinctly useful and shows very good results; for whereas 1 out of every 2 children was definitely below the limit on admission, only 1 out of 5 is below when leaving. And this would probably show an even better result had it not been for the fact that quite an appreciable number,

classed as malnourished on leaving, have left for a special reason—school-leaving age, leaving the district, admission to other institutions. And in addition to this some of the malnourished are among those still in the school who, as explained, are included in this series, and they will doubtless pass the limit in course of time.

The Cases Analysed.

A further analysis of the cases is of great interest; other investigators have shown that the children under the limit are usually taller for their ages than were those in more normal condition of weight.¹² The paucity of data in these figures did not permit an analysis by sex and age for this purpose; but it was shown that the children who remained malnourished tended to put on more height than either those malnourished cases becoming normal, or the normal group. To make any comparison feasible, two year groups were taken together and the average annual increase in height worked out. The results were as given in Table III.

TABLE III.—Average Increase in Height per Year.

—	Ages.	Group 1. Malnourished remaining malnourished.	Group 2. Malnourished becoming normal.	Group 3. Normal.
		Inches.	Inches.	Inches.
Boys ..	6-7	2.4	1.7	1.8
	8-9	1.9	1.6	1.8
Girls ..	8-9	2.0	1.8	1.8
	10-11	1.9	1.7	1.8

Group 1 in Table III. make rather more than the average increase in height and this agrees with other investigations,¹² so that it would appear that there has been a retardation in height as well as in weight, and that as soon as favourable circumstances permit there is not only an improvement in weight, but a definite and greater than average increase in height. One of the problems met by the nutrition worker and noted by W. R. P. Emerson is the fact that as fast as children who are underweight make gains in weight, their height increases as well and the new height calls for additional weight.

According to age, sex, and height, the average annual gain in weight can be obtained from the Baldwin-Wood tables, and this expected average gain for the whole period of stay at the school has been worked out for each child individually in the Torquay series. On comparison with the actual gain during the same time, figures were obtained as given in Table IV.

TABLE IV.—Average Gains in Weight (in Pounds).

—	Group 1. Malnourished remaining malnourished.		Group 2. Malnourished becoming normal.		Group 3. Normal.	
	Expected gain.	Actual gain.	Expected gain.	Actual gain.	Expected gain.	Actual gain.
Boys ..	14	13½	10	12½	8½	10½
Girls ..	12½	12	12	16	9½	13

It is seen that the children remaining malnourished gain approximately as much as the average expected increase in weight (although they have put on more than the average in height), but the other groups gain considerably more than the expected addition of weight (and they only gain the average in height). So while the gain in weight in Group 1 is not sufficient to bring the children above the malnutrition standard, yet in the other two groups the increase is quite adequate, even taking into account the fact that the extra height automatically demands a higher standard of weight in the Baldwin-Wood scale. In other words, it is frequently found that the advance in weight sufficient to bring children up into the safety zone is accompanied by more than the expected increase in height for the same period. A prominent investigator recently made the dictum that if the inches are looked after, the pounds will look after themselves; but it is better to consider both, the one in relation to the other, for obviously it is evident that a number of children have at the start more inches than they are able to sustain by pounds.

Conclusion.

This investigation can be criticised on several grounds; paucity of data is apparent, especially when considering averages, and the division into age- and sex-groups, and an American scale has been used on English children. But it shows that further investigations on these weight-height-age tables may possibly be profitable in exploring the wide

field of nutrition and malnutrition, especially with the object of obtaining uniformity of classification as far as possible. The weight-height ratio is important to the extent that the mortality experience of insurance companies indicates definitely significant facts in this connexion; at younger ages a limited amount of overweight appears an advantage, associated with more favourable mortality records. According to the report of the Joint Committee of the Actuarial Society of America and the Association of Life Insurance Medical Directors (New York, 1922), underweight for height is a serious impairment in early adult life. Persons 30 per cent. underweight have a 50 per cent. excess mortality at these early ages. It would seem that the records of insurance companies indicate that there is an optimum weight—that is, a weight-height ratio in relation to age that is associated with the most favourable mortality experience—and that this optimum weight, or best build, is not the average. Such, then, indicates the obvious importance of this ratio. And, further, any such standard is to be desired not only as a help to ascertain all cases of unsatisfactory nutrition, but also to assess and check the available methods of dealing with this defect. In connexion with the results in this survey, the findings may certainly claim to show something of the improvement brought about in malnourished children by continuous open-air school work; for although it is only a day school in Torquay, yet it has been carried on winter and summer alike through the whole period, and no heating at all has been required in the class rooms or rest sheds—probably due to the mild equable climate. And the method of assessment is independent of the personal factor present to some extent in clinical work.

I wish to thank Dr. T. Dunlop, M.O.H., Torquay, for permission to use the figures and details required in this investigation.

BLACKBURN'S HEALTH WEEK.

THE corporation of Blackburn some time ago set up a "Publicity Committee on Health," and as part of the outcome of its activities a health exhibition lasting for 10 days was opened on Feb. 11th, the object being to educate the citizens, so that, in the words of the Mayor, they might, by their own efforts and knowledge, avoid sickness and disease, and thus help to secure for every child born in Blackburn a birthright of mental and bodily health. The public are asked to recognise that health is not merely the avoidance of disease, but a positive condition of the body to be brought about and maintained by the observance of proper rules of living. The exhibition was entirely educational and the commercial element was intentionally excluded. The importance of fresh air, sunshine, and of good and proper feeding inspired the salient exhibits, which were organised by the Central Council for Infant and Child Welfare. The corporation of Glasgow sent exhibits to show the value and importance of fresh air, and the gas, electricity, cleansing, and other departments of the Blackburn Health Department also lent exhibits. Special efforts were made to instruct visitors on the importance of pure milk. From the exhibition handbook we learn that Blackburn has had for many years special powers for preventing the sale of tuberculous milk, the veterinary surgeon being empowered to visit farms from which such milk is being sent to the borough. Blackburn's gross expenditure by the health committee—less income from Government grants—is £16,805, which works out at a net charge per head of the population of 2s. 7½d. and the net charge on Blackburn ratepayers expressed as a penny rate

is 5·9 pence—an extremely moderate rate. During the 10 days the exhibition was open daily short lectures were given on health topics; the town's maternity home, welfare and school clinics were open for inspection; and "Health Sermons" were preached on Sunday at most churches and chapels in the town.

THE COST OF SCIENTIFIC PUBLICATIONS.

It has been decided by the Treasury, as a result of representations from the National Union of Scientific Workers, to provide in the 1925-26 estimates for an increase in the grant to the Royal Society towards the cost of scientific publications from £1000 to £2500. It is not intended that the Royal Society should spend the grant on its own publications, but that it should administer it for the benefit of subsidiary societies—such as the biochemical, the chemical, and the geological societies—which are hard put to it to find money for making known the results of their research work. It is pointed out in the current issue of the *Scientific Worker* that, with an additional £1500 available, the Royal Society may be in a position to consider more applications from individual research workers for assistance to enable their results to be published.

PUBLIC HEALTH IN BASUTOLAND.

Mr. E. G. Dutton, Acting Government Secretary, in his report for 1923 states that treatment at the Government dispensaries was given to 48,318 patients during the year. In the hospitals 2377 patients were treated. The number of surgical operations performed was 2133. The general health of the territory was good, and, with the exception of typhus fever and small-pox, there were no serious epidemic diseases; 68 cases of measles, 49 of chicken-pox, 9 of diphtheria, 111 of whooping-cough, and 22 of enteric fever were reported, all more or less sporadic. No case of scarlatina was recorded. Typhus fever is still epidemic in all the districts in the territory; 958 cases were reported, with 120 deaths. This is a considerable increase over the previous year, due in part to the regulations regarding notification being more strictly observed. Propaganda as regards prevention has been carried out in various ways and assistance has been given by the native press. Small-pox of a mild type was epidemic during the year; 671 cases with 14 deaths were reported. Most of the cases occurred in the central districts of the country. This is a continuation of the epidemic reported in 1922. The following were notified during the year: influenza, 337 cases, no deaths; dysentery, 56 cases, 1 death; pneumonia, 106 cases, 2 deaths; cerebro-spinal meningitis, 8 cases, 1 death. Free treatment for syphilis continues to be given, and it is noted that many are availing themselves of the privilege. Venereal disease is accountable for much ill-health and disablement in spite of the efforts of the medical officers to instruct in the way of clean living and personal hygiene. The Leper Settlement continues to do good and useful work. The inmates at the end of 1923 were 213 males and 254 females. There were 66 admissions, 5 readmissions, 42 deaths, 10 desertions, and 31 discharges during the year. The various forms of treatment are being vigorously pushed with much success, and a considerable number await discharge in the near future. There has been a marked fall in the death-rate in the asylum, which may be attributed partly to the intensive modern treatment now given and partly to the more favourable early-stage condition of the patients now being admitted. The employment of the more able-bodied lepers in useful and remunerative work contributes much to their happiness and health. The men get 1 acre of land and the women ½ acre to cultivate, the produce of which is bought by the Government. Two large solaria have been built for the treatment of both sexes by graduated exposure to sunlight. The farm produced good crops during the season and there has been an ample supply of milk, together with potatoes, fruit, and vegetables to supplement the dietary. These have gone a long way to improve the general health of the patients. Basutoland, a native territory in South Africa, is bounded on the west by the Orange Free State, on the north by the Orange Free State and Natal, on the east by Natal and East Griqualand, and on the south by the Cape Province. Its area is 11,716 square miles. The altitude varies from 5000 feet to 11,000 feet above sea-level, and the climate is, on the whole, healthy. The census of 1921 showed 495,937 natives and 1603 whites, besides 1069 coloured and 172 Asiatics.

INDEX TO "THE LANCET," VOL. II., 1924.

THE Index and Title-page to Vol. II., 1924, which was completed with the issue of Dec. 27th, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2.

Milroy Lectures

ON

EPIDEMIC DISEASES OF THE CENTRAL NERVOUS SYSTEM.

Delivered before the Royal College of Physicians of London on March 5th, 10th, and 12th, 1925.

By ARTHUR SALUSBURY MACNALT, M.A.,
M.D. Oxf.,

A MEDICAL OFFICER OF THE MINISTRY OF HEALTH; EXAMINER
IN PUBLIC HEALTH IN THE UNIVERSITY OF OXFORD.

LECTURE I.*

I WOULD in the first place wish to thank the College for the honour they have conferred on me by their appointment to deliver the Milroy Lectures for 1925. I have taken as my subject the epidemic diseases of the central nervous system. It is one which accords with the intentions of the founder of these lectures, touching as it does upon a consideration of the part which contagion plays in the origination and spread of acute or pyrexial disease.

INCREASING SUSCEPTIBILITY OF THE CENTRAL NERVOUS SYSTEM TO ATTACKS OF EPIDEMIC DISEASE.

Acute poliomyelitis, encephalitis lethargica, and cerebro-spinal meningitis, from the very nature of the region of the body attacked, are of serious and grave import; cerebro-spinal meningitis, in view of its frequently fatal issue in the acute stage, poliomyelitis and encephalitis lethargica chiefly by reason of their disastrous after-effects.

Since 1897 epidemics of poliomyelitis have occurred in England and Wales, fortunately not to the extent to which they have been met with in America. The years of the war have familiarised us with severe outbreaks of cerebro-spinal meningitis on a scale of severity previously unknown in this country. In the last year of the war, 1918, encephalitis lethargica appeared in our midst as a recognisable disease, and has subsequently, in succeeding years, manifested itself in epidemic form (see table). As will after-

wards be shown, there are grounds for belief that this increased incidence of epidemic nervous diseases is associated with an increased susceptibility on the part of nervous tissue in certain individuals to these diseases.

To what causes are we to attribute this increased and rapidly increasing susceptibility of the central nervous system to attacks of epidemic disease? It

will be found that no decisive answer that would accord with the prevailing trend of epidemiological inquiry can be given to this interrogation at the present time. It will not be unprofitable, nevertheless, to give some attention to the possible explanations, not necessarily incompatible, that may be advanced upon the subject.

(1) The first view may be described as the *Communication Theory*. Modern methods of transportation bring individuals in contact with one another more frequently than has been the case in the past, and so increase the facilities for the spread of epidemic infection. Infection may thus travel with the speed of modern transport from one country to another or from one part of the same country to another. The increase of large towns, the tendency of urban populations to assemble in crowded gatherings enhance the opportunities for personal infection, and a disease which in the eighteenth and nineteenth centuries might have been sporadic or endemic is rendered epidemic or pandemic in the twentieth century.

There is much substance in this view as regards increase of opportunity for infection. The transportation of troops to and fro in all parts of the world during the war undoubtedly favoured epidemics of influenza and cerebro-spinal meningitis. At the same time it will be recalled that both cerebro-spinal fever and poliomyelitis had been increasing in frequency and assuming epidemic form prior to the war, while the increase in encephalitis lethargica subsequently to those years possibly implies an increasing susceptibility of nervous tissues to infection. Modern methods of communication, therefore, cannot supply the whole explanation.

(2) *Epidemic Cycles*.—It may be suggested that these diseases of the nervous system occur from time to time in epidemic cycles, and that at present such an epidemic wheel is turning full circle among mankind. It is well established in the case of the acute zymotic diseases that such epidemic cycles occur.

Hirsch,¹ in tracing the history of epidemics of cerebro-spinal meningitis has shown that the disease occurs in epidemic waves or periods. In this respect it resembles the periodicity of influenza, but, owing to its much lesser morbidity, it exercises less devastating effects on populations, advances much more slowly, and in periods of epidemic prevalence its distribution is less world-wide than influenza. Unfortunately, the rapidity of modern transport and more frequent international communication appear to be modifying this latter feature of cerebro-spinal fever, as may be seen from the many countries affected in the recent epidemic period.

The recurrence of these epidemic waves of cerebro-spinal fever is irregular. Our best information on this point comes from the United States, where epidemics have been recurring since 1898, some of them on a large scale. The figures of incidence of cerebro-spinal meningitis in non-epidemic periods indicate, as for influenza and measles, that the approach of an epidemic wave of cerebro-spinal fever is signalled by an increase in the number of cases; a similar increase in sporadic cases is seen in the wake of an epidemic. In endemic centres of the disease the advent of an epidemic can be anticipated by noting the rising increase of cases in the notification returns. It may be the case that poliomyelitis and encephalitis lethargica behave epidemiologically like their sister disease and from time to time appear in epidemic periods. If so, we may be under the hand of a heavy epidemic visitation. We have no authentic records of previous epidemic cycles of poliomyelitis and encephalitis lethargica; possibly, as regards these two diseases, we are still in the shadow of their first epidemic periods. In each disease it is established that the *materies morbi* is always present in affected countries. For the initiation of an epidemic wave it may be surmised that several factors come into play from time to time, which, either by increasing the virulence of the causal

* Lectures II. and III. will be published in subsequent issues of THE LANCET.
5297

virus or by lowering the defensive forces of the human organism, or by the exercise of both influences, bring about an epidemic.

(3) "*Epidemic Constitution*" of *Influenza*.—More comprehensive than the last hypothesis, but in some respects allied to it, is the view of those who would group influenza, cerebro-spinal fever, poliomyelitis, and encephalitis lethargica as arising from some common condition. This view has been succinctly summed up in the following terms²:—

Various epidemiological records go far to establish: (a) that the epidemiological features of the cycle of years within which influenza explodes are different from those of the influenza-free cycles; (b) that preceding epidemic influenza there is often a rise in general morbidity of the population, an "epidemic constitution" develops favourable to influenza, there are early though often mild and atypical clinical forerunners of the disease, and parallel or allied clinical maladies are seen; and lastly (c) that there are concurrences, similarities, and inter-relationships between outbreaks of cerebro-spinal fever, poliomyelitis, and outbreaks of influenza, bronchitis, and pneumonia.

The term "epidemic constitution" is admittedly vague, and the evidence is conflicting with regard to the favouring part played by influenza in the aetiology of epidemic nervous disease. In the first place influenza, in the absence of identification of the causal organism, defies definition. The authorities who have had most clinical experience in regard to epidemic diseases of the central nervous system fail to recognise an association between them and influenza.

Many cases of epidemic poliomyelitis and encephalitis lethargica are mistaken for influenza in the first instance through failure to diagnose the prodromal stages of these maladies. Until we know more of the aetiology of influenza, and until the concept of an epidemic constitution favouring the occurrence of epidemic nervous diseases can be demonstrated more clearly, it seems well to regard cerebro-spinal meningitis, poliomyelitis, and encephalitis lethargica as distinct and separate diseases, and unwise to assume that all cases of disease occurring in the course of a widespread epidemic are necessarily an integral part of the epidemic. If in doing so the epidemiologist is sinning against the light he can at all events plead that the light should be made more luminous.

(4) *Soil and Seed in Epidemic Nervous Disease*.—In another view which I venture to bring before you consideration is given both to influences at the present time reacting on the central nervous system in man, and to the possibilities of an origin of new species of organisms which can give rise to epidemic nervous disease. On this hypothesis, which is not exclusive of the views already considered, there are two factors involved, the special susceptibility of the region of the body attacked and the neo-parasitic nature of the virus of the disease attacking, or to use a hackneyed metaphor, both the soil and the seed play their part. The central nervous system of man is harnessed willy-nilly to the chariot of modern progress; it is made to work not necessarily more efficiently, but at a more rapid pace; it is exposed day by day to demands upon its attention, claims on its vitality, and shocks and vicissitudes which the nervous systems of our forefathers never knew, and which we in our childhood barely envisaged. We are now able to travel distances at speeds which the past would regard as magical. This Ariel-like facility of motion and of concentrating our labours of necessity causes increased strain on the nervous system. In towns the retina is always fatigued by coloured posters and moving vehicles by day, and at night by electric light and changing light signs. The world gets through an increased amount of work in the shortest possible time; but the penalty is paid in "nervous breakdowns," neurasthenia, and other manifestations of nervous fatigue to which the dwellers in the pastoral age were strangers.

It is a truism of medicine that a disease is prone to attack an individual at the weakest or most fatigued point of bodily resistance. To this rule the central

nervous system is no exception. Nissl found that marked changes, indicated principally by disintegration of the chromatin granules, occur in the body of every nerve-cell after severance of its axis-cylinder. In the case of a child of 6 years suffering from poliomyelitis, seen by me during the course of an epidemic of this disease in 1917, the patient had fractured the left forearm two months previous to the onset of poliomyelitis. The muscles paralysed were those of the injured arm. Possibly, by a process of ascending degeneration from the nerves involved in the traumatic injury, the anterior horn cells innervating the muscles of the left forearm were injuriously affected, and the virus of poliomyelitis subsequently attacked the anterior cornua at their most vulnerable point. Similarly, we may postulate that fatigued or over-worked tissues of the central nervous system are thereby rendered more susceptible to the attacks of invading organisms. The pioneer work of Hughlings Jackson had already begun as far back as 1870 to point out that study of the individual patient comes before the study of the disease, for a disease is rarely typical, but is modified by the characteristics of the patient. The environmental conditions under which the human nervous system functions to-day are modified; the system itself is subjected to more frequent and urgent stimuli than formerly. May not the soil thus be prepared to receive the seeds of disease?

In this connexion it is of interest to note that the outbreaks of encephalitis lethargica in Vienna, Paris, and this country first appeared at a time when individuals had been exposed to the mental strain of several years of war, and that the cases occurred then chiefly in large urban centres of population where such strain was likely to be more acutely felt.

The possible evolution of new organisms affecting the human central nervous system is the second and most important factor in the hypothesis under discussion.

In speculating upon the possibility of the advent of the organisms of epidemic nervous disease this might have taken place in one of the following ways: (1) The organisms may have been in the first instance harmless parasites of man and in the struggle for existence have taken on inimical characteristics. (2) They may have been organisms causing catarrh of the naso-pharynx or gastro-intestinal tract which now tend to affect the brain and spinal cord. Captain S. R. Douglas, F.R.S., in a personal communication, draws attention to the fact that the organisms of poliomyelitis and of epidemic encephalitis are filtrable viruses, like those of the "common cold." The catarrhal forms of these diseases seen in the abortive or mild types afford some support for this view. (3) The organisms may resemble the pneumococcus in being widespread amongst human beings and capable, under certain conditions, of giving rise to autogenic infection. As regards cerebro-spinal fever, the bacteriological evidence is not in favour of this suggestion. (4) The organisms may have been saprophytes in nature but are now assuming the rôle of human parasites. For this hypothesis no evidence has as yet been forthcoming. (5) They may be epizootic organisms which are becoming increasingly transmissible to man and afterwards from man to man. The evidence bearing upon this question is discussed subsequently. For any one of these possibilities a lowering in resistance of the defensive powers of the human nervous system would be an important contributory factor.

EPIDEMIC NERVOUS DISEASE IN ANIMALS.

The information in regard to similar epidemic diseases of the central nervous system in the lower animals is scanty, and there appears here to be a large *terra incognita* unexplored by the comparative pathologist. Considering first cerebro-spinal fever, Sophian³ says that pure meningitis in domestic animals is uncommon, and that many of the so-called cases of meningitis are toxæmias in which spinal and cerebral symptoms occur.

The evidence for an epizootic form of poliomyelitis was equally indefinite until the outbreak described by Cleland and Campbell.⁴ This was an epidemic form of encephalomyelitis which occurred in the late summers of 1917 and 1918 and was restricted almost entirely to certain dry inland parts of New South Wales. The disease affected human beings as well as horses, cattle, sheep, and goats. Breinl⁵ regarded the disease as a clinically aberrant form of poliomyelitis in which the brain was extensively involved, and Flexner,⁶ who had opportunities of examining post-mortem material from the outbreak, confirms this view.

In the investigation of encephalitis lethargica the possibility of a similar disease occurring in the lower animals has not been ignored. Parsons has placed on record a full account of the investigations made in this country on the subject. A number of alleged outbreaks of encephalitis lethargica⁷ affecting dogs and cats, and in one instance farm horses, were inquired into, but on the whole the clinical signs displayed did not suggest encephalitis lethargica beyond being coincident in point of time with a high general incidence of that disease throughout the country. Much has been made of the recent discovery that spontaneous encephalitis due to protozoan-like parasites as described by Wright and Craighead⁸ and Veratti and Sala,⁹ occurs in rabbits, mice and geese.¹⁰ McIntosh¹¹ has pointed out that the histology of this spontaneous encephalitis differs from that of encephalitis lethargica, whether occurring naturally in man or experimentally produced in animals, while the staining of the parasites in the spontaneous form supplies another point of differentiation.

There is, therefore, only evidence that poliomyelitis may affect simultaneously man and animals in epidemic form, as in the outbreak described by Cleland and Campbell. And in this outbreak the infection may have been transmitted from man to domestic animals. There is no substantial evidence for the suggestion that the increasing incidence of epidemic nervous disease is due to the transmission of epizootic organisms to man.

Cosmic Influences.—In considering the epidemiology of the three diseases it will be found that each one of them is subject to certain influences which it is customary to class together as causes predisposing to the disease. Overcrowding and lack of free ventilation in cerebro-spinal meningitis is a good example. In particular, all these diseases show an epidemic seasonal prevalence peculiar to each one of them. Cerebro-spinal fever prevails in the winter, encephalitis lethargica in the spring, and poliomyelitis in the late summer and early autumn. Sudden changes of temperature seem to be favourable to the meningococcus; continued hot weather, as in 1911, aids the spread of poliomyelitis. In the case of the latter disease it may be that our much maligned climate has saved us from epidemics of the magnitude seen in the United States.

It is established that the *materies morbi* of cerebro-spinal fever and of poliomyelitis and by analogy that of encephalitis lethargica also is always present in the upper respiratory passages of persons in affected countries in non-epidemic periods. The epidemiologists of the seventeenth and eighteenth centuries paid much attention to the part played by weather in promoting epidemics of disease. It may prove well in the future to follow in their footsteps, and to study more closely than has yet been done the influence of meteorological conditions in the initiation of epidemics of the central nervous system.

EPIDEMIC NATURE OF CERTAIN DISEASES OF THE CENTRAL NERVOUS SYSTEM.

It is within comparatively recent times that the epidemic nature of certain diseases of the central nervous system has been recognised, and in regard to two of them at all events—namely, poliomyelitis and encephalitis lethargica—this knowledge is far

from widespread among medical practitioners. The reasons for this are possibly the impression of earlier teaching when nervous diseases were regarded as rare and exceptional and always due to a chronic process, a thrombosis or arterial affection or some other degenerative change giving rise to sclerosis of the nervous tissue, quite apart from any question of infectivity; the sporadic character assumed by types of epidemic nervous disease, and the failure to recognise mild and abortive forms as connected with the same disease, have occluded and still continue to mask the infective nature of many small outbreaks.

Cerebro-spinal Fever.

The senior disease of the triad on record is cerebro-spinal meningitis. This is first known to have occurred at Geneva in February, March, and April 1805; it caused the death of 33 persons, but, curiously enough, the Commission appointed by the Swiss Government were of opinion that there had not been enough cases to merit the name of epidemic.

In spite of many subsequent large outbreaks the contagious character of cerebro-spinal fever was largely ignored until the war period, when the disease became epidemic in this country and elsewhere, and was extensively studied and reported upon. In 1914 the findings as to infectivity of the disease published by Netter and Debré,¹² by Sophian³ and others, had not, as now, become common knowledge. The Local Government Board made cerebro-spinal fever compulsorily notifiable throughout England and Wales in 1912, and thus far the epidemic and infectious nature of the disease was officially recognised.

Belief in its sporadic character was strengthened by the disconnected way in which the bulk of the cases occur in epidemics, by statistical evidence that only a relatively small proportion of those exposed to infection ever contract the disease, and that direct contagion from case to case is exceptional. On the other hand, a number of instances of direct infection are recorded by Reece¹³ and others.

The secret of these apparent anomalies has been disclosed partly by the epidemiologist and clinician in recognising mild and abortive cases of cerebro-spinal fever, which at first sight bore no apparent relation to the cardinal nervous symptoms manifested by severe examples of the disease, but chiefly by the bacteriologists in their discovery of the healthy carriers of the meningococcus and of the various types of virulent and avirulent meningococci. The research work on the bacteriology and serology of cerebro-spinal fever organised by the Admiralty and the War Office with the invaluable coöperation of the Medical Research Council is beyond all praise, and the additions made to scientific knowledge will for ever remain on record as a testimony to the good that came out of the evil of war and disease.

Here I would especially mention the typing of meningococcal strains done by Gordon¹⁴ and the valuable work of my colleague, Dr. J. A. Glover,¹⁵ in relation to overcrowding, the carrier-rate and many other phases presented by cerebro-spinal fever. The President¹⁶ in the Lumleian Lectures on Cerebro-Spinal Fever, delivered in 1919, has made so full an exposition of the subject which he has enriched by his own researches, that for many years to come writers on the same theme can but follow in his pioneer footsteps.

The apparent breaks and gaps in the chain of case-to-case infection in cerebro-spinal fever are due to several reasons. In the first place, the delicate characters of the meningococcus limit the opportunities for transference of the disease outside the human body. Secondly, while contacts of cases of cerebro-spinal fever are infected by the meningococcus, it does not of necessity follow that they develop the disease. They may possess enough powers of resistance to tide over the time of potential attack, so that the invading organism perishes in their nasal and oral passages without penetrating to the meninges: in this case the chain of infection is completely broken; or, as occurs

more commonly in epidemic periods, the contacts harbour the meningococcus for a greater or less length of time as transient or permanent carriers and transmit the infection to more susceptible individuals. A third possibility is that the contact develops the disease in a mild or slight form, the existence of which escapes recognition.

Glover¹⁵ has made clear the important fact that a wave of high carrier-rates precedes and accompanies an outbreak of cerebro-spinal fever. In other words, there is a carrier epidemic (for the most part entirely devoid of symptoms) in advance of and in association with the much smaller case-epidemic. Whilst endorsing Arkwright's dictum, "the number of the carriers constitutes the epidemic," and accepting the commonly recognised views that individual lack of susceptibility and healthy carrier transmission suffi-

previously recognised poliomyelitis as an infection, but to Medin belongs the credit of classifying poliomyelitis as an epidemic disease. Medin in his paper states that Bergenholz noted 13 cases occurring in the department of Norrbotten in 1881. Groups of cases of poliomyelitis were reported in Europe and in America from 1887 to 1897. W. Pasteur,¹⁹ in 1897, described the first English epidemic, recording poliomyelitis in seven members of one family at Much Hadham, a small village in Hertfordshire. Hospital cases in London were collected and described by Dr. Thomas Buzzard²⁰ in 1898 and Dr. F. E. Batten²¹ (1902-04). About this time the classical monograph on the subject was written by Ivor Wickman,²² of Stockholm, the pupil and assistant of Medin, who made a thorough study of the epidemiology, and first recognised and described the so-called abortive or non-paralytic cases.

EPIDEMIC POLIOMYELITIS. DIAGRAMMATIC REPRESENTATION OF SPREAD OF INFECTION.

ciently account for the apparent sporadicity of the disease, even in times of epidemic prevalence, one is impelled to believe that the factor of direct personal infection plays no small part in the epidemic spread of cerebro-spinal fever, masked though it may be by the failure to diagnose mild associated forms of the malady and by the rapidity of modern methods of transit. This factor is more clearly demonstrated when an epidemic of cerebro-spinal fever has lasted in a country for some length of time. Foster and Gaskell¹⁷ adduced evidence of the disconnected way in which cerebro-spinal fever prevailed in England in 1914-15. Later on, however, Reece¹⁸ pointed out that the general distribution of troops among whom the epidemic started, the greater number of which were stationed in the Eastern and South-Eastern parts of England, influenced the prevalence. The modern records indicate, therefore, that there is ample evidence for the recognition of cerebro-spinal fever as an infectious epidemic disease.

Acute Poliomyelitis.

Still later in point of time of recognition as an epidemic disease comes poliomyelitis. It was not until 1890 at the International Medical Congress, Berlin, that Medin,¹⁸ a Swedish physician, described in some detail the epidemiological features of poliomyelitis, based on his study of 44 cases in the Stockholm epidemic of 1887, and suggested that the infection might be spread by mild or anomalous and unrecognised cases. Strümpell and Pierre Marie had

From 1908, when a small outbreak of eight cases of poliomyelitis was observed at Upminster, in Essex, by Dr. W. W. Treves,²³ up to the present time, epidemic outbreaks have occurred in appreciable numbers in this country, and have been placed on record by Reece,²⁴ Farrar,²⁴ Macewen,²⁵ and others. All the large epidemics abroad, notably in America, began to impress the infectious character of the disease on the medical profession. Pathological investigations at this stage by Landsteiner and Popper,²⁶ by Flexner and Lewis²⁷ in New York, by Leiner and von Wiesner²⁸ in Vienna, and by Landsteiner and Levaditi²⁹ in Paris, supplemented the mass of epidemiological and clinical evidence assembled in regard to the infectious nature of poliomyelitis.

It is now well established that infection may be conveyed by (1) persons suffering from an acute typical attack of poliomyelitis; (2) individuals having a mild or atypical form of the malady; (3) healthy persons who have been in close contact with the sick but have not themselves developed an attack; and (4) chronic carriers who have apparently quite recovered from a previous typical attack. Infectivity in acute cases is greatest during the early stages of the malady.

The subjoined diagrammatic representation of the spread of infection relates to a small outbreak of acute poliomyelitis in Esher and the Dittons Urban District and Epsom Rural District, which I investigated for the Central Health Authority in 1917.³⁰

It is interesting to note in this example in how many cases of poliomyelitis the possibility of infection by direct contact was demonstrated. Where this evidence is lacking the chain of infection appears to be maintained through the medium of a healthy carrier. Attention has already been called to this feature of epidemics of poliomyelitis. Müller³¹ lays stress upon the fact that adults who have been in contact with infection may act as "carriers" of poliomyelitis and quotes illustrative examples. In the New York epidemic of 1916 the virus of poliomyelitis was recovered from apparently healthy persons who had been in contact with children ill of the disease.

Encephalitis Lethargica.

There remains now for consideration the infectious nature of encephalitis lethargica. In studying this question the epidemiological evidence already available in regard to cerebro-spinal fever and acute poliomyelitis greatly facilitated an understanding of the behaviour of encephalitis lethargica. No evidence has been elicited that the virus of this disease is conveyed through intermediate agencies, such as water, soil, food, clothing, biting insects and flies, &c. The question then arises as to the spread of the disease by personal contagion.

In the early days of the study the evidence as to case-infection was scanty. Bernard and Renault,³² referring to the French Ministry of Hygiene's inquiry, state that out of 464 cases notified in 55 departments from January to May, 1920, there was no obvious case of contagion. Smith³³ in the United States, out of 181 cases, records a similar experience. In 1919, from the evidence already obtained, I inclined to the view that encephalitis lethargica was an epidemic and infectious disease³⁴; the same opinion was early expressed by Netter.³⁵ In 1918 a few mild cases of the disease were noted, but no clear association between these and declared nervous forms of the disease was traced. Yet, even then, a considerable number of cases occurred in definite areas, such as Birmingham, Sheffield, and Tredegar, although apparently unrelated to one another, while in certain districts, as, for example, in the county borough of Stoke-upon-Trent, a restricted topographical distribution of the cases was observed.³⁶ More recently the tendency of encephalitis lethargica to be concentrated in its distribution in certain areas has also been observed in isolated agricultural districts. Dr. Dittmar, of the Scottish Board of Health, notes six cases of the disease in a rural part of Ross-shire arising during the years 1922 and 1923. As regards infection in utero or placental transmission, there are cases reported by Harris,³⁷ Kononowa,³⁸ Novaes and Sousa,³⁹ and others.

I have reported multiple cases of encephalitis lethargica in families which occurred at Mansfield in 1918, and at Eastbourne and Weybridge in 1919. Since 1919 I have collected notes of a number of additional examples of multiple cases of encephalitis lethargica in England and Wales, and other cases have been recorded from time to time in various parts of the world. An interesting example is that communicated by Van Boeckel⁴⁰; at Ruddervoorde, in West Flanders, in 1919, where the disease attacked four families who were closely inter-related. Of 26 persons, 17 were attacked, and 4 of these died. Kling and Liljenquist,⁴¹ of Stockholm, found, in February, 1921, that encephalitis lethargica was prevalent in certain villages in Lapland, the morbidity rate varying from 7.1 to 45.0 per cent. In some families several members contracted the disease simultaneously, and in two houses almost all the inhabitants were affected. Side by side with the severe and typical cases were catarrhal and febrile cases, cases with slight affection of the ocular movements, and a few cases of obstinate hiccup. Special attention has been devoted to this subject in France by Netter,³⁵ who records a number of multiple cases in households.

The most striking example of an institutional outbreak of encephalitis lethargica was investigated by me at Derby, England, in August, 1919.⁴² In a home for girls an explosive outbreak of illness occurred affecting 12 persons (females) out of 22 persons (females) resident in the institution. The following were the dates of onset of the disease: Two patients were attacked on August 14th, 1919; two on the 15th; four on the 16th; two on the 17th; one on the 19th; and one on the 27th. No further cases of illness occurred after August 27th. The range of age-incidence was from 15 to 40 years; the stress of the disease fell on the lower ages (15-18 years).

It will be recalled that with a filtered emulsion of cerebral tissue from the first case Prof. McIntosh⁴³ succeeded in transmitting a fatal lethargic illness to a monkey, and on histological examination of the monkey's brain Prof. Turnbull found lesions identical with those of human cases of encephalitis lethargica. The clinical features of the Derby outbreak were so characteristic of encephalitis lethargica that from this aspect alone little doubt can be felt that one was dealing with cases of the disease. Furthermore, two of the girls that recovered from the acute illness have subsequently manifested the typical mental sequelae of encephalitis lethargica. John and Stockebrand⁴⁴ have reported a similar outbreak in an asylum at Mulheim in the summer of 1922. Here 28 cases with 13 deaths occurred in 20 days, six being in nurses and two in doctors. Dysphagia and ophthalmoplegia were frequent symptoms.

The existence of these multiple cases and epidemic outbreaks in encephalitis lethargica would not necessarily imply that the disease is communicable from one person to another. The multiple cases might have been infected with the virus of the disease from a common source. But the following appears to be an undoubted example of personal contagion. A woman, aged 63, was attacked by encephalitis lethargica on Dec. 5th, 1918. She was removed to a nursing home on Dec. 17th. A nurse, aged 39, who took charge of the patient at night in the nursing home, fell ill with the same disease about Dec. 26th or 27th. Both patients recovered. Instances are also on record where a patient admitted to hospital for some other disease has acquired encephalitis lethargica, presumably from another patient who suffered from this disease and was in an adjoining bed. We are also aware of the existence of mild and ambulant cases of illness in association with declared cases of encephalitis lethargica; several instances of the kind were encountered during the considerable rise of incidence of the disease that occurred in 1924 in Liverpool, Sheffield, and elsewhere; through their medium the conveyance of infection; from one person to another seems to be more than probable.

The presence of these "carriers" in encephalitis lethargica indicates that the disease is in accord with cerebro-spinal fever and poliomyelitis as one in which the pathogenic agent is more frequently present in the human organism than the clinical evidence would imply. The work of Eastwood, F. Griffith and Scott,⁴⁵ &c., has already established this conception as true for cerebro-spinal fever. Also the cases first reported by S. A. Kimmier Wilson,⁴⁶ Parkes Weber,⁴⁷ Crouzon,⁴⁸ and others of symptomatic paralysis agitans following on an attack of encephalitis lethargica lead to the suggestion that certain cases of paralysis agitans in its chronic form may have their origin in an undetected attack of encephalitis lethargica, although Pierre Marie and Mlle. Lévy⁴⁹ and Cruchet oppose this view.

It is well not to disdain the study of the natural history of disease and the grouping of allied diseases. A considerable time elapsed before the infectious nature of cerebro-spinal fever and poliomyelitis was established. Recognising the similar features in these diseases to those of encephalitis lethargica and applying the knowledge we possess of them to the study of the latter disease, the conclusion seems to be justified, and is gaining universal

acceptance, that encephalitis lethargica is equally infective, and liable to manifestation in epidemic form.

Lettsomian Lectures

ON

WOUNDS AND OTHER INJURIES IN THEIR MEDICO-LEGAL ASPECT.

Delivered before the Medical Society of London

By SIR BERNARD SPILSBURY, M.B., B.Ch. Oxf.,

LECTURER IN MORBID ANATOMY AND HISTOLOGY, ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE; HON. PATHOLOGIST TO HOME OFFICE.

LECTURE II.*

In the last lecture I considered in some of its aspects the medico-legal problem presented by contusions, laying emphasis upon the rapid failure of the circulation after death and its bearing upon the post-mortem development of bruising. I then devoted some time to an analysis of crushing injuries of the chest and abdomen, pointing out how frequently serious internal injuries occur without any external manifestation. In the last part of the lecture injuries produced by firearms were described, with special reference to the means of distinguishing self-inflicted injuries from those produced by others.

Incised wounds are produced by weapons having a cutting edge which is drawn along or struck against the skin; similar injuries may be produced by objects having a sharp edge—for example, broken glass. An incised wound generally has a length greater than its depth, and retraction of its edges causes it to gape to a greater or less extent; the elasticity of the skin in part accounts for this, but the retraction of the divided muscles is the cause of the wide gaping of wounds which penetrate deeply. When examined shortly after infliction the skin and deeper structures are cleanly and smoothly divided; the margin is not bruised unless the weapon is blunt. Where the skin is lax the movement of the weapon, especially if it is blunt, may draw the skin along until it becomes folded. If the fold is incompletely divided intact skin will separate the two portions of the wound; if completely divided the skin margin will be notched. The blood-vessels are divided cleanly in an incised wound, blood escapes freely, and spurting from small arteries

* Lect. I. was published in THE LANCET last week. Lect. III. will appear in a subsequent issue.

produces characteristic rows of blood spots on surrounding objects.

Lacerated, in contrast with incised, wounds are produced by objects which tear the tissues, such as nails, machinery, hard projections, or the teeth of animals; they have ragged and generally contused margins and irregular bases, and the adjacent skin surface is often abraded. The roots of hairs which are in the line of the wound are not torn across but project from the edges of the tear. Blood-vessels are crushed as well as torn, and bleeding is generally less copious than in incised wounds, but if the wound should be situated in the vulva, where the tissues are very vascular and are readily torn or crushed, fatal hæmorrhage may result from a lacerated wound.

In one variety of lacerated wounds blood-vessels in the deeper part of the skin may escape injury to a large extent, forming bridges across the wound; these injuries will bleed even less freely, and are found in parts where the skin is immediately over bone; the majority of scalp wounds are of this nature and similar wounds are found along the orbital margins, on the shins, and over bony prominences. Violent contact with a hard, smooth surface produced by a fall or by a blow with a blunt weapon, crushes and splits the skin in the area of most marked compression against the bone. Such an injury, although it is clearly a lacerated wound, is often described as a cut.

Cut-throats form the most important group of incised wounds, a large proportion of dangerous incised wounds occurring in this region; they are almost always suicidal or homicidal.

The only example in my series of a fatal accident was in a drunken man who in falling drove his head through a pane of glass; he was found dead with three incised wounds on the right side of the head; they ran horizontally, the uppermost crossing the pinna and extending into the scalp, the middle situated just below the ear being 4 in. long and extending down to the spine, the third, a very superficial wound, being at a slightly lower level. No important blood-vessels were divided. A fall through glass often produces multiple wounds in the same direction, and the situation of these injuries is unlike that of suicidal or homicidal wounds.

A fatal case of suicidal cut-throat has generally only one deep wound in the upper part of the neck; beginning on the left side, it may be far back, it extends across the front and in some cases to the right side of the neck; it is straight or only slightly curved, has a slight downward inclination and crosses the front of the neck at or above the level of the thyroid cartilage. Sometimes the wound runs horizontally across the front of the neck at a lower level; occasionally the wound is on the right side, when it runs more obliquely from above downwards and forwards and does not cross the middle line. These are the positions of the wounds when the weapon is held in the right hand. A suicide will sometimes insert the weapon into the first cut, making one or more additional incisions which increase the depth or extent of the wound.

Thus an elderly man cut his throat late at night in a quiet street, inflicting an injury in the upper part of the right side of the neck. The wound was 3 in. long and extended forwards and downwards from a point 2½ in. below the right ear almost to the middle line half way between the thyroid cartilage and the chin. The injury consisted of two cuts, one from the hinder end for rather more than half the length of the wound; the knife was then inserted into the wound and the cut extended further forwards. A deep notch in the skin indicated the junction of the two cuts. The common facial vein was divided at a short distance from the internal jugular vein. The man walked about 200 yards after closing the weapon, a pocket-knife, and placing it in his pocket; he was found dead on the footpath; in his hand was a blood-stained handkerchief which had been used presumably to try and staunch the blood. Death was due to air embolism through the common facial vein. The man

was probably making his way to his doctor, having repented after he had cut his throat, but he became exhausted and withdrew the handkerchief from the wound, and air entered the open end of the vein.

A suicide sometimes cuts his throat in front of a mirror, in order to see that the weapon is placed as he desires; almost invariably the neck is bared before the attempt is made. If the weapon is again inserted into the cut the structure most often damaged is the larynx, in which several cuts may be found when there is only one skin incision. It frequently happens that a suicide makes a number of other attempts on the neck before producing the fatal wound. These tentative cuts are very superficial; they start near the main wound, and run approximately in the same direction; a dozen or more may be present, when they will be close together and may run into one another. A suicide sometimes injures other parts of the body before cutting his throat; a series of parallel cuts may be found across one wrist, usually the left, or across the front of the left chest, but it is rare for a suicide to employ the same weapon both for stabbing and cutting in different parts of the body. Such a case is described later in the lecture.

An unusual case with a wound in another part was that of a Japanese gentleman who first made a half-hearted attempt at suicide by hara-kiri, a wound 7½ in. long being found across the front of the abdomen; the wound penetrated down to the deep fascia. He had then cut his throat in no uncertain fashion, inflicting an injury 6 in. long in the upper part of the neck on the right side: the wound started three-quarters of an inch from the middle line at the back, and passed forwards and downwards to the middle line in front; at the back were eight separate tentative cuts. The wound gaped widely and the thyroid cartilage was exposed and was cut in three places, none of the cuts passing completely through it; the internal jugular vein was completely divided, there was a small opening in the common carotid artery, and the body of the fourth cervical vertebra was nicked in two places. A suicide occasionally takes poison and then cuts his throat, and I have seen two cases in which a suicide drank strong hydrochloric acid.

In the following case the plane of the wound was unusual for a suicide. An elderly man had a wound 7½ in. long across the upper part of the front of the neck; it was straight and horizontal, extending further on the left side with the right end undercut. The wound penetrated deeply upwards and backwards immediately above the hyoid bone; the front wall of the pharynx was divided for more than an inch and the cut extended into the root of the tongue on the left side. The only vessel divided was the left common facial vein, close to its termination. Air entering through the cut vessel had caused death from air embolism. This case and the one already described are the only two suicidal cut-throats in the series in which death was due to air embolism; in each case the common facial vein was divided.

The next two cases are examples of multiple suicidal injuries of the air passages; they are seldom seen excepting in the insane and those who are in delirium. The first was that of a man who cut his throat whilst suffering from lobar pneumonia with delirium; the wound crossed the middle of the neck, was 3 in. long and gaped widely; it consisted of at least two deep cuts, and there were incisions in the exposed cartilage and another in the upper part of the trachea. Close to and parallel to the main wound were ten superficial cuts. There were six superficial cuts in the right cheek; on the front of the chest were 12 similar cuts internal to the left nipple; they were parallel, extended from left to right and slightly downwards, and lay within an area measuring 3 in. by 3 in. There were five parallel superficial cuts on the right wrist, several on the front of the left wrist, one of them deeper, and a number of superficial parallel cuts and one

deeper cut on the inner side of the right thigh 4 in. above the knee.

In the other case a woman whose mind was affected by excessive drinking attacked a man who was in bed with her, drew a knife across his throat, and inflicted a superficial injury; she then cut her own throat, and a gaping wound $3\frac{1}{2}$ in. long ran horizontally across the front of the neck. In the exposed air passages were four deep incisions, one through the first ring of the trachea, a second between the cricoid and thyroid cartilages, and two others close together through the upper part of the thyroid cartilage, where a piece of the cartilage was missing. The margins of the skin incision on the right side were notched in two places by the additional cuts in the air passages. The thyroid gland was cut in several places, but the only blood-vessel opened was the right external jugular vein. There were four tentative cuts close to, and parallel with, the gaping wound.

Occasionally laceration is found in the deeper part of an incised wound. A man who cut his throat had a gaping horizontal wound $4\frac{1}{2}$ in. long across the middle of the neck, chiefly on the left side; the wound was deep in the middle and undercut at the right end; the larynx had been opened by a deep cut through the thyroid cartilage and a part of the left sterno-mastoid muscle was cut. On the left side the wound penetrated deeply and appeared to be lacerated, and a tear extended along the left wall of the œsophagus for a distance of 2 in. The deeper part of the wound had been torn open with the hands after the throat was cut.

Except in lunatics suicidal wounds in the neck usually have a fairly characteristic position and direction. Homicidal, whilst sometimes simulating suicidal wounds may have any position and may run in any direction. The difference is well seen when multiple wounds are present; in suicidal injuries it is rare to find more than one deep wound in the neck, any other injuries being superficial tentative cuts; in homicidal cases there are no tentative cuts, but several deep wounds may be found. When two injuries are so severe that either alone would produce rapid loss of consciousness, as, for example, when the carotid arteries are cut on both sides in two separate incisions, we have the strongest presumption of homicidal causation.

A very unusual case was one in which a husband was put on his trial for the murder of his wife by cutting her throat. At the time of her death she was six months pregnant and was suffering so severely from chorea gravidarum that she had great difficulty in feeding herself and had to be assisted in dressing. A medical man who had examined her three days before she died found her incapable of any continuous muscular effort of the nature of a grip; she suffered much from restlessness and sleeplessness. Early one morning her husband ran out of the bedroom bleeding from wounds which he said had been inflicted by his wife, who had attacked him with a razor whilst he was lying beside her in bed. One wound extended along the right jaw from the angle to the middle line, the bone was exposed, and the facial artery divided. Two wounds, each 4 in. long and skin deep, were found on the back of the left side of the neck. There were cuts on the palmar aspect of three fingers of the left hand.

On entering the bedroom the woman was found dead on the floor by the side of the bed with a pile of bedclothes around her. When she was turned over an open razor was found near her right hand. There was a pool of blood on the bed and in the blood a hairpin and much hair, one strand being 8 in. long and $\frac{3}{4}$ of an inch thick. Splashes of blood were found for $5\frac{1}{2}$ ft. above the level of the bed on an adjacent wall; they had been flung from the blood-stained razor when it was raised to inflict the later injuries.

On examination of the dead body the following injuries were found. There was a long, deep, incised wound around the right side of the neck from the

middle line behind almost to the middle line in front. At the back it penetrated to the spine and at the side completely divided the common carotid artery and the internal jugular vein and opened the œsophagus. On the left side of the neck was a similar wound extending from the middle line at the back, where it overlapped the other wound, to the front of the neck where they almost met. On this side the internal jugular vein was opened and the common carotid artery almost completely divided. A third wound crossed the lower part of the back of the scalp; it was 4 in. long and about three-quarters of an inch deep; there was a superficial cut on the right side of the front of the neck. There were also superficial wounds on the right ear, the lower lip, on the palmar aspect of the right ring and index fingers, and across the knuckles of the left index and middle fingers. As the husband and wife were the only persons concerned, the facts were capable of three different interpretations—the one given by the husband, that his wounds were caused by his wife who had then taken her own life; another, that the man's injuries were inflicted by his wife and that he had wrested the razor from her and inflicted the injuries upon her. The third explanation was that the husband had attacked and killed his wife and that his injuries were self-inflicted. The wife had shown no sign of insanity, and in view of the severe chorea from which she was suffering it seemed improbable that she could have grasped a razor so firmly as to have inflicted several serious injuries upon herself, whilst the slight cuts on the ear and lip might well have been the misdirected attempts of another person. The wound across the back of the scalp could only with difficulty have been self-inflicted. When the two deep wounds in the neck are considered, the infliction of one of them would be followed by such a rapid fall of blood pressure that there would scarcely have been time before consciousness was lost, for the weapon to have been transferred to the other hand for the infliction of the second injury. But the division of the muscles on one side of the neck would have produced instant flexion of the head to the other side and would have rendered impossible the production of a clean cut on that side as a self-inflicted injury. An assailant, grasping her by the hair, could have slashed the neck, producing all the injuries; the hair found on the bed indicated that the head was held when the cut through the scalp severed a portion of the hair, causing it to fall on the bed when the grasp was relaxed. In my view the woman's injuries could not have been self-inflicted. The wounds on the palmar aspects of the fingers of the husband and wife might well have been caused in each case by an attempt to grasp the weapon wielded by the other, and the wounds on the knuckles of the woman's left hand were suggestive of injury inflicted by another person.

The husband was found not guilty of the murder, the jury probably being influenced by the fact that he had injuries upon himself, one at any rate of a severe nature, and also by the evidence that he was a quiet, sober, hardworking man, whose relations with his wife had always been happy. The verdict was equivalent to one of suicide, but I am certain that the injuries could not have been self-inflicted.

One of the most difficult homicidal cut-throats to distinguish from a suicidal injury is that inflicted when the assailant attacks the victim from behind and draws the weapon across the front of the neck. The position and the direction of the wound depend upon the relative positions of the two persons; it generally makes a clean sweep of all the soft tissues in the path of the weapon; it is often more curved than a suicidal injury, and the plane of the wound may differ from a suicidal cut, but in some cases it closely resembles one.

An important distinction between homicidal and suicidal cut-throats is that the suicide almost invariably bares the neck, but the murderer cuts through the clothing. When the injury is inflicted from behind the assailant makes a sweeping movement which starts before it reaches the throat and passes beyond the

limit of the wound; clothing may be cut in its passage before or after the wound is inflicted, and blood will be found on the edge of the cut if the weapon has already passed across the neck. The two next cases are examples of the value of information obtained from cuts upon the clothing.

In the first case the dead body of a young married woman was found one morning in a quiet lane. She had a gaping wound 4 in. long on the front and right side of the neck; the internal jugular vein was completely divided, the larynx was opened in front and on the right side, and the oesophagus was incised at its upper end. A fur collar round the dead woman's neck had been cut by the weapon in line with and to the right of the wound. A razor belonging to the husband and found in his bedroom had dried blood upon it, and adhering to the blood were rabbit hairs similar to those which formed the fur collar. The weapon had cut the collar after inflicting the injury; this gave the direction in which the cut had been made. The dead woman was wearing a knitted jumper, and across the front of the left shoulder of the article was what appeared to be a tear. On close examination this appearance was found to be due to a clean cut, the material becoming unknitted and giving the appearance of a tear; no blood was present on the cut edges. The weapon, therefore, had been drawn across the front of the left shoulder, and then passed across the neck, cutting through the fur collar after it emerged from the wound. The cuts in the clothing afforded a clear proof that the injury was a homicidal one. The husband was charged and was convicted of murder.

In the second case a young woman had her throat cut in the road by her lover from behind. A gaping wound was found on the front and right side of the neck; it was between 5 and 6 in. long and was unusually curved, the right extremity passing at the back almost vertically upwards behind the ear. The common carotid artery and the internal jugular vein had been opened in the wound, and there was a large cut in the lower part of the larynx. After the injury had been inflicted the girl ran through a gate and along a winding garden path in the dark, opening the back door and passing through the scullery into the kitchen where she pointed to her throat before she fell, having covered a distance of about 75 yards. She was wearing a beaver hat with a broad brim, and a clean cut passed through the brim on the right side; the lower edge of the cut was smeared with blood, showing that it had been made by the weapon after it had passed through the neck.

In four cut-throat cases, two of them suicidal, air embolism was the cause of death; in none of these was there any injury to the main arteries, and in none were the large veins completely divided. The internal jugular vein was opened in one, in two others the common facial vein was completely divided close to its termination, and in the fourth case another tributary close to the internal jugular vein. Air embolism occurs when the internal jugular vein is opened, or when a large tributary is cut across close to the main vessel rather than when the main vein is completely cut through. In two cases, both homicidal, the cervical sympathetic nerve had been partly or completely divided; in these cases the pupil was smaller on that side than on the other.

One case in the series was a suicidal incised wound of the abdomen in an elderly woman; there was a cut 2½ in. long in the middle line of the abdomen below the umbilicus. She was admitted into hospital with a large part of the small intestine and the omentum protruding through the wound; these were replaced and the wound sutured, but she died shortly afterwards. The weapon, a razor, was found folded up and placed in a box in the bedroom in which she was found. Suicide was also indicated by the presence of several superficial cuts radiating from the umbilicus, chiefly on the left side, 14 superficial parallel cuts on the front of the left wrist, a similar cut on the left thenar eminence, and many others on the left side of the neck.

The last example of an incised wound was in a man who was found by the night watchman in the lavatory of a theatre after it was closed for the night. He was bleeding from a wound in the left arm and died shortly after he was found; a small blood-stained razor was found upon him. The wound was slightly more than 2 in. long and crossed the front of the left forearm 1½ in. above the wrist. Several tendons were divided and the radial artery was completely severed; the incision extended down to the radius. No other wound was found and the organs were pale from loss of blood.

STABS.

Punctured wounds or stabs are injuries produced by instruments which pierce the skin; the weapon must therefore be pointed. These wounds generally have a depth greater than their length. Stabs form a class of injury intermediate between incised and lacerated wounds. The appearance of the wound depends upon the weapon which has been used to produce it; a sharp-edged and pointed knife, especially if it has a double edge, cuts as it pierces the skin and deeper tissues and the wound will everywhere be clean cut. A knife with a thick back produces a wound which is incised where the edge cuts its way, and lacerated where the back tears through the tissues. A pointed instrument which has no cutting edge, such as a butcher's steel, or a hatpin, only tears the tissues.

The edges of stabs require very careful scrutiny to determine whether they are mainly incised or lacerated in character, and it is impossible to give an opinion when suppuration has developed in the wound. A large variety of pointed articles has been used for the production of stab wounds—pins, needles, hatpins, knives, skewers, and fragments of broken glass; some of these, such as broken glass, are responsible chiefly for accidental injuries, and the same is true of pins, needles, hatpins, &c., but suicidal and homicidal injuries have also been inflicted by such means.

The small size of the skin wound and the depth of penetration render it difficult by external examination to judge the direction and to estimate the damage; there may be little external bleeding if the weapon has penetrated into one of the body cavities. The difficulty of judging the direction by probing the wound is increased when divided muscles retract and alter the shape of the wound.

In one case a man was stabbed behind the ear and the wound ran horizontally and penetrated into the spinal canal; when it was explored with a probe it appeared to run down the neck, the sterno-mastoid muscle having been divided and retracting to such an extent as to produce a pocket below the entrance wound which was almost 2 in. deep.

The degree of damage to the deep tissues in a wound also depends on the weapon; one which combines a sharp-cutting edge with a point will pierce and cut everything in its path and will be far more dangerous to life than a blunt-pointed object having no cutting edge, which will tend to push aside rather than pierce blood-vessels, or viscera such as the lungs, which yield readily to pressure.

Accidental stabbing injuries rarely endanger life apart from subsequent sepsis. I have collected 18 cases of deaths from stab wounds; none of these were accidental, 11 were homicidal, and the remainder suicidal. Many of the homicidal and suicidal stabs were inflicted with a weapon which had a cutting edge, and the length of the wound depended upon the extent to which the cutting surface had been used.

A suicide stabbing himself in the chest with a pocket knife sometimes withdraws the weapon from the wound by an exact reversal of the movement which has inflicted the injury; no further injury to the skin may be produced than that required to drive the weapon into the tissues, and the surface wound may have a diameter, when allowance is made for the elasticity of the skin, rather less than the breadth of the penetrating portion of the weapon; the edges of such a wound may be everted as the weapon is gripped

by the skin during withdrawal. In homicidal cases the movement of the victim during the infliction of the injury is likely to cause the wound to be enlarged during withdrawal, and the surface wound will then be of greater width than the blade of the weapon.

Suicidal stabs are usually made over vital areas, the front of the chest in the region of the heart being the commonest situation. The wounds are generally multiple, are situated within a small area, and have much the same direction in the tissues. Suicidal stabs in the neck are infrequent, but a combined incised and stab wound is occasionally seen: a cut is made in the neck and the point of the weapon is driven deeply into one part of it. Stabs and incised wounds are frequently associated in suicides, the failure to produce the desired result by stabbing causing the suicide to use the cutting edge of the knife on other parts of the body. In five stabbing cases incised wounds were found on the neck or elsewhere. In one case death was brought about by drowning in a bath after a number of stabs and incised wounds had been inflicted; in two others, both insane persons, the suicide also jumped from a window.

One of these cases was a young woman who had become insane as the result of influenza and pneumonia during the epidemic of 1918: she inflicted injuries upon herself with a table-knife, four superficial incised wounds being found on the upper part of the neck on the left side; they were typical suicidal wounds, parallel and running slightly downwards towards the right. There were 11 superficial cuts on the lower part of the front of the left chest mainly internal to the nipple. She then thrust three table-knives down her throat, one passing down the oesophagus into the stomach where it cut the mucous membrane. Another knife had stabbed through the epiglottis and the posterior pharyngeal wall and was then pushed down in the cellular tissues in front of the spine to the posterior mediastinum: it penetrated into the right pleural cavity, in which it lay free. The third knife followed the track of the second and was found with the blade projecting into the pleural cavity, the upper half of the handle being in the mediastinal tissues; the pleura contained half a pint of blood. She then jumped from the bedroom window, falling a distance of over 20 feet which caused a bruise on the temple and some meningeal hæmorrhage.

The suicide who drowned himself in a bath had an unusual distribution of stabs associated with incised wounds. There were six wounds on the neck: two were short incised wounds on the right side of the neck a short distance below the ear and the angle of the jaw respectively; another incised wound four and a half inches long was at a slightly lower level—at its front end it penetrated upwards and backwards for one inch towards the floor of the mouth. There were two other slight cuts in the neck, and a stab wound immediately above the sternum which extended for a distance of one and a half inches to the left and slightly upwards. There were at least seven tentative cuts close together on the upper part of the left side of the neck. There were two stab wounds in the left chest below the nipple: one was superficial, the other penetrated into the left pleural cavity. There was a superficial stab immediately below the sternum and there were two stabs in front and on the inner side of the left elbow. No important structures were divided in any of the wounds.

An injury which combined the characters of an incised wound and a stab was found in the upper part of the right side of the neck of a man who had committed suicide. The wound was almost two inches long and was parallel to the lower border of the jaw and extended behind the angle: it was very superficial in front, but at the back it penetrated for almost three inches, passing backwards and slightly inwards, dividing the internal carotid artery, the internal jugular vein, the vagus nerve, and the sterno-mastoid muscle: it extended into the erector spinæ muscles behind. There were three other superficial cuts

close to the main injury, and one on the right temple. A suicidal stab wound in an old man passed through the upper part of the anterior abdominal wall obliquely downwards, pierced the gastro-hepatic omentum, and penetrated into the body of the pancreas.

A difficult case was that of an old man 78 years of age, who was bedridden and lived with his wife aged 80. According to her statement he was left for half-an-hour propped up in bed, and on her return was found dead, with blood on the front of his clothes, a large pair of scissors lying upon his abdomen. He had a stab wound on the front of the left chest a short distance above and to the inner side of the nipple. The weapon had entered the chest through the fourth intercostal space, crossing the left ventricle of the heart and penetrating into the right: the pericardium contained much blood. He had a transverse cut an inch long on the left side of the neck extending slightly across the middle line: it appeared to be a single wound and had entered the upper part of the larynx where several parallel cuts were seen in the thyroid cartilage. He was in a very feeble condition and it was thought that the injuries might have been inflicted by his wife, who was also very feeble, but it was found that the stab in the chest had not passed through his vest and night-shirt, both being unbuttoned in front and the edges of the night-shirt turned in. A verdict of suicide was returned.

Stabs through the left ventricle of the heart do not always allow blood to escape from the cavity of the ventricle, the wound being closed by muscular contraction and later being sealed up by clot. This was the case in a man, obviously insane, who stabbed himself over the heart with a penknife, and attempted to cut his throat, inflicting 18 superficial wounds on the left side of the neck: he then threw himself out of a window. The stabs were five in number, situated close together on the front of the left chest wall internal to the nipple; they all penetrated into the pleural cavity in front of the lung, two passed through the parietal pericardium close together and the cavity contained half an ounce of blood clot. One passed completely through the anterior wall of the left ventricle close to the interventricular septum, where a small opening was present at the base of one of the papillary muscles. The fall from the window had fractured the right lower jaw and both thighs, extending into one knee-joint; he also had a lacerated wound on the forehead. He survived the injuries for a few hours and did not die from the penetrating wound of the heart, the small amount of blood in the pericardium having escaped from the edges of the wound and not from the interior of the ventricle.

Homicidal stab wounds, in contrast with suicidal, are more frequent in the neck, the chest taking second place, and the abdomen coming last. These wounds often have a position and direction which would render it difficult or impossible for them to have been self-inflicted. Thus a woman was stabbed, and 13 wounds were found upon her body. The wound which was mainly responsible for her death was a stab about an inch and a half long, situated in the lower part of the neck on the right side immediately above and parallel to the outer part of the clavicle. The wound penetrated for about 4 in., running inwards and slightly downwards, dividing one cord of the brachial plexus, opening the right subclavian artery, and entering the pleura immediately below it, cutting the apex of the lung and penetrating to the outer surface of the trachea. The right pleura contained 15 oz. of blood. Another stab four-fifths of an inch long entered the lower part of the back of the left chest $3\frac{1}{2}$ in. from the spine, and extended for more than 2 in. into the lower lobe of the lung. The pleura contained about 4 oz. of blood. There were two stabs at the back of the left chest internal to the scapula, each measured 1 in., and they ran upwards and inwards for a distance of $2\frac{1}{2}$ and 3 in. respectively through the subcutaneous tissues and muscles. There was a stab $1\frac{1}{2}$ in. long in the upper part of the neck on the left side close to the scalp; it penetrated for more than 2 in. inwards and slightly

upwards without injuring any important structures. There were several irregular cuts, most of them superficial, on the lips, the left cheek, the neck, and the left upper arm; no large blood-vessels had been divided in these wounds. The chief wound in the neck could only with difficulty have been self-inflicted; the three wounds at the back of the chest were clearly homicidal injuries, and the injuries on the face were unlike suicidal wounds.

Since homicidal stabs may pass in any direction it is particularly difficult to estimate the extent of the injury, and a part of the track of a wound may be missed during an operation to repair the damage. In a case of stabbing in the abdomen where a small knife had been used, the wound in the abdominal wall was half an inch long and was situated 2 in. above the pubic bone immediately to the right of the middle line. The track of the injury was obliquely downwards and backwards, passing into the peritoneal cavity and transfixing a coil of small intestine 18 in. above the ileo-caecal valve; it then passed through the parietal peritoneum on the right pelvic wall and extended for a distance of 3 in., opening the external iliac vein. Acute abdominal symptoms developed two hours after the injury had been inflicted; an operation was performed, a large quantity of blood was evacuated from the peritoneum, and the wound in the intestine was found and sutured, but the further course of the track was not discovered and the patient died a few hours later from peritoneal hæmorrhage.

A stab which penetrates into one of the body cavities—e.g., pleura or spinal canal—may cause death from internal hæmorrhage with little or no external bleeding. In the case already referred to of a homicidal stab wound behind the ear, the victim was a young Canadian soldier who was on leave in London during the war and who was known to be in possession of a fairly large sum of money. He was struck on the side of the head, fell down immediately, and died in a few minutes. On examination a stab was found directly below the right mastoid process. The wound was horizontal and just under half an inch in length; the track passed inwards and slightly backwards, the right occipital artery was completely divided, and the weapon had pierced the dura mater in the occipito-atlantal space without injuring the spinal cord. Hæmorrhage from the artery passed inwards along the track into the subdural space and surrounded the whole of the spinal cord, and a large part of the base of the brain, causing death from meningeal hæmorrhage. The depth of the wound was almost 2 in. It was suggested that the injury might have been caused by a fragment of broken glass, but it was clear that a wound so narrow and so deep could not have been caused by that means.

Homicidal stabs in the neck sometimes run very obliquely downwards, penetrating into the chest and producing rapidly fatal injuries. In one case a wound was found immediately above the sternum slightly to the right of the middle line; it was half an inch long and vertical in position. The weapon passed downwards and slightly backwards in the superior mediastinum, opening the left innominate vein, and extending through the left parietal pleura. Blood from the injured vein accumulated in the pleural cavity, which after death contained over six pints. There was a cut in the shirt corresponding with the wound in the neck.

In another case there was a wound on the front of the neck on the left side 2 in. above the clavicle; it was one and three-fifths of an inch long and was vertical; it passed almost directly downwards through the sterno-mastoid muscle and the internal jugular vein, entering the left pleural cavity at the apex, cutting the subclavian artery, and penetrating into the apex of the left lung for a distance of three-quarters of an inch. Hæmorrhage from the cut vessel was almost entirely internal, and 3½ pints of blood were found in the left pleural cavity.

In a case of murder a wound in the neck, like one of the suicidal cases quoted above, combined the characters of a cut throat and a stab. It was 5½ in. long, situated in the upper part of the front of the neck more on the right than the left, and ran slightly upwards from left to right. The larynx had been opened between the thyroid cartilage and the hyoid bone and gaped widely. On the left side of the neck the wound penetrated deeply as a stab, dividing the sterno-mastoid and other muscles, dividing completely the left common carotid artery, and partly dividing the internal jugular vein. It cut through the intervertebral disc between the fourth and fifth cervical vertebrae from its margin to the middle line and half divided the spinal cord. The wound appears to have been made by a single stroke, the weapon being thrust deeply into the left side of the neck, and withdrawn across the right side of the neck.

In three homicidal cases death was due to injury of the heart. In one the weapon passed completely through the left ventricle and interventricular septum, a large amount of blood escaping into the pericardium and left pleura. In another the weapon penetrated from above and transfixed the pulmonary artery, passed through the right ventricle into the left auricle. In both cases death followed rapidly, but in the second case the victim ran a distance of 40 yards before she fell unconscious.

In the third case the weapon passed through the front wall of the left ventricle close to the interventricular septum, the cut on the inner surface of the ventricle being small; he survived the injury for about 22 hours. An operation was performed and the wound in the heart was sewn up. At the post-mortem examination the wound in the heart was closed by blood-clot; a small amount of blood was found in the pericardial cavity which had escaped from the wound.

In two homicidal cases death was caused by injury of the lung. In one there were two wounds, one penetrating the right lung from the front, the other the left lung from above, the stab having been made immediately above the inner end of the clavicle; death occurred three days later. In the other case the injury was inflicted on the front of the left chest immediately below the clavicle; it penetrated into the lung, and after death, which occurred 12 days later, the pleura contained between five and six pints of blood. Hæmorrhage from a peptic ulcer in the stomach, which began a week after the injury was inflicted, and continued to the end, probably determined the fatal issue.

DONATIONS AND BEQUESTS.—The late Mr. James Maxwell Grant Proffit, Glenluce, Wigtonshire, and Portland-place, W., after the fulfilment of several personal bequests, left his residuary estate, subject to his sister's life interest, for a trust fund of which one-half is to be applied for inquiry into the nature, cause, prevention, treatment, and cure of tuberculosis, and one-half for a similar inquiry regarding cancer, as a board of special trustees shall decide. The value of the bequest will be about £160,000 net. The board of the trust fund is to consist of the chairman for the time being of Barclays Bank and chairman of the Chartered Bank of India, Australia and China, the President of the Royal College of Surgeons of England, and the President of the Law Society. The trustees may, amongst other powers, apply the funds of the trust in financing persons or institutions conducting such research, in the equipment and (or) endowment of institutions or laboratories for this purpose, and in publication of the results of such researches. —An anonymous donor has presented £50,000 to the Governors of the Royal Technical College, Glasgow; a condition of the gift is that the sum is to remain as the permanent capital of the College. —Sir Robert Hargreaves Rogers, Bexley, Kent, left £500 each to Bexley Cottage Hospital and Bexley Victoria Homes. —Following the gift of £1000 to Newark Hospital by Mr. H. W. Adams, a local councillor, from charity funds at his disposal, it was announced at the governors' meeting on Feb. 24th that £5000 had been subscribed towards the erection of a nurses' home by Mr. Harry Coulthby, of Cleveland, U.S.A. The donor was born at Claypole, a village near Newark.

THE DIAGNOSIS OF INCIPIENT INSANITY IN YOUNG ADULTS.

BY H. S. LE MARQUAND, M.D., M.R.C.P. LOND.,
ASSISTANT MEDICAL OFFICER, THE MAUDSLEY HOSPITAL.

THROUGH the controversies which have arisen over the psychological teachings of Freud, psychiatry has been brought of late to the notice of the general practitioner more than ever before.

As the family doctor deals with the earliest signs of bodily disease, so he is the first to treat the early symptoms of mental disorder, seeing the patient in the most hopeful stage. But in the cases with which this article deals, the onset of symptoms is so insidious that the serious nature of the trouble is often not suspected until this early period has passed. It would, then, be an advantage if one could indicate some of the signs and symptoms which would place the doctor on his guard; and this is likely to be especially important in the near future when there will be an extension of the voluntary boarder system and of clinics for border-line cases.

Forms of Insanity Occurring in Adolescence.

For the purpose of classification, the form of psychosis occurring in adolescence may be grouped under three headings: (1) Confusional psychosis; (2) manic-depressive psychosis; (3) dementia præcox. This article does not deal with the first two conditions, for they are not peculiar to early adult life, and their sudden onset and acute mental symptoms remove them from the category of "incipient insanity." But the third heading—dementia præcox—includes a large number of cases which are peculiar to early adult life, and which present grave difficulties to early diagnosis because of their insidious onset, when the symptoms may closely resemble those of one of the common neuroses. It is with these cases that this article is intended to deal.

The term dementia præcox has been much criticised because it covers such a variety of cases, but even if it be not the clinical entity which it was once supposed to be, yet its use is a great convenience. It includes those patients who exhibit an inability to grapple with their environment, a consequent turning away from reality to live in a phantasy world of their own, with a progressive deterioration, both emotional and intellectual.

Insidious Development of Dementia Præcox.

The gradual onset of the trouble must always be in the mind of the general practitioner, as he may be consulted at any stage of the disorder. The usual course may be summarised as follows. A shy, seclusive individual gradually becomes more and more self-centred and apart from his fellows. He loses interest in outside affairs and his emotions and desires weaken. Less and less energy remains for his life's work, and he retires from it to occupy himself with phantasy. Misconstructions, to which he was ordinarily rather prone, develop into delusions, as he projects his own apathy on to others. Hallucinations add to the variety of his phantasies and he loses the power of distinguishing one from the other. Abnormality of conduct follows. Then, in many cases, the apathy becomes profound, intellectual deterioration sets in, and a condition of profound dementia results. If this gradual trend of events be remembered, the disorder may be suspected when no very definite signs are present; but, as well as the general consideration of the case, there are certain signs of a more definite character which may be noticed in the early stages.

Early Dementia Præcox: Some Characteristic Signs.

Mental Signs.—A point in the history which is worth noting is the occurrence of moral lapses or minor

disorders of conduct. For example, one patient had been in constant trouble in the R.A.F., for committing petty offences "out of bravado"; another had twice stolen worthless articles. In the first case it was two years before mental trouble was suspected.

The psychotic often interpolates in his conversation which may be otherwise quite rational, remarks of an unusually bizarre character. Such expressions as "my heart feels compressed and light"; or "I feel I have no blood in my body," are the type of thing met with. The fantastic character varies from a remark put in a slightly unusual form to such a statement as "I have no roof to my mouth," an obvious delusion. When pressed to explain these statements the replies of the patient are unsatisfactory and inconsequent. Often the symptoms of which he complains are put in a peculiar way. He may state that one part of his mind is struggling with the rest, or that one part appears to be talking to the other. While he may then have insight into the symptom, a remark such as that not infrequently heralds the more complete dissociation which will be shown by hallucinosis. Symptoms of this kind should be regarded with suspicion.

The question of insight is one of some interest. While a neurotic always has insight into his condition—that is, he always ascribes his condition to some natural physical cause—a psychotic typically has no insight. But in these early cases of dementia præcox the patient usually ascribes his condition to something wrong with his brain or his head, and he only gradually loses insight as the disorder progresses. A stage is often passed through when the patient sometimes has insight into his condition and at other times has not; or he has insight into some symptoms and not into others; or, again, he has insight into the several symptoms themselves, but plainly does not recognise the profound nature of the disability from which he is suffering. For example, one extremely depressed patient quickly recognised that her depression was abnormal and best treated by medical means, whilst still maintaining the truth of the delusions on which the depression was founded.

Though an intellectual defect is not a marked sign in an early case as a general rule, yet it may occur and must not be overlooked. For example, one apparently intelligent patient could not remember the date of the beginning or end of the war, nor any particulars of its onset and progress.

Physical Signs.—The text-books describe a number of physical signs of dementia præcox. Amongst these, transverse wrinkling of the brows, wasting of the thenar and hypothenar eminences, and the tendency of the hair to stand on end are not commonly found in the early stages. But complaint may be made of the development of hair in unusual situations. Sweating may be confined to one limb or portion of the body. The circulation in the extremities is frequently poor, and the patients show cold and blue hands and feet which may become oedematous.

Dementia Præcox and the Neuroses.

Now it is during the long development of the psychosis that confusion with one of the neuroses may occur. All the neuroses merge into one another in indefinable grades, but for the sake of convenience they may be classified into: (1) Neurasthenia; (2) hysteria; (3) compulsion neurosis; (4) anxiety neurosis. Cases will be described in which the diagnosis between these conditions and that of dementia præcox was uncertain, so that the important points may be exemplified.

Dementia Præcox and Neurasthenia.—CASE 1. Male, T. B., aged 26, clerk. This patient came up to hospital complaining of an excessive feeling of tiredness, with a consequent loss of energy. He suffered from headache and slept badly. He gave a clear account of himself, showing no cognitive defects. He expressed affection for his mother, and anxiety at not having the energy to work for her. He said that he was seclusive, and he appeared to be unduly suspicious of a brother-in-law who lived in the house. He

had not been subjected to any particular stress, but he had worried a good deal over the habit of masturbation which he had endeavoured to suppress.

From these symptoms a diagnosis such as neurasthenia would be considered fairly safe, and the condition would be regarded as likely to clear up with simple advice as to rest or a holiday in the country. The patient was admitted to hospital in February, 1923, and on investigation some rather more suspicious facts were elicited. Lately he had become rather surly and morose, he had sometimes locked himself in his room, and he had been heard tramping about at night. However, considering the case as a whole, he showed then but little affective change. What change there was, was not towards the apathy of a dementia præcox, for he showed symptoms of anxiety. There was no cognitive impairment. He showed considerable loss of conative power in his lack of energy. After some months in hospital, where his behaviour was normal, he was discharged "recovered" and went back to work. For six months he remained at work, but with ever-increasing difficulty. He became apathetic and hopeless, and on readmission to hospital he passed into a state of catatonic stupor, in which he remained for five months. Now (Feb. 25th) he has recovered to the extent of working well in an institution, but he shows some intellectual deterioration.

In general, this case shows the importance of keeping the possibility of a psychosis in the mind in a young adult with neurasthenic symptoms, and shows also the value of a careful history revealing the change which had been taking place in the disposition. There were other points of interest. When he first came up to hospital his symptoms were few, yet his disability was profound—a disability not limited, as in many neurotics, to his work, but extending to all his activities. He had had no extra strain to cause a breakdown. In fact, the early dementia præcox often seems to be absolutely disabled, with, as it were, very little to show for it. His symptoms are few, often consisting, as in this case, of headache and loss of energy with a feeling of anxiety about his condition, the cause of which he cannot understand. On the other hand, the typical neurotic complains of many symptoms, of which he is rather pleased to talk, and despite which he is often able to continue his work satisfactorily. In the early stages the degree of disability of the dementia præcox is much more pronounced. It was noticeable that when this patient began to relapse a game of tennis produced complete exhaustion and great depression.

Another point of interest is that when first seen he showed anxiety about his condition. Despite the text-book description of dementia præcox, this anxiety is usually found in the early stages rather than the apathy which is characteristic of the later phases of the disorder.

Dementia Præcox and Hysteria.—Hysteria and dementia præcox are conditions which usually appear to be entirely distinct, yet cases arise in which the diagnosis is at first by no means easy.

CASE 2.—Male, aged 24. He was the eldest of nine children, and had won several scholarships while qualifying as a teacher. After teaching for three months he broke down, becoming "nervy" and excitable, unable to reply to questions or to stand noise. He stopped at home and was treated by a doctor for about a year before admission to hospital. On admission, he gave a coherent account of the development of his illness, showing no cognitive defects at all. He usually spoke in a whisper, saying he had lost his voice, but sometimes this was nearly normal. He had a habit of holding all his muscles rigid for a few minutes at a time, and his explanations were vague. He did not express much anxiety about his condition, and quickly settled down in the institution, yet sometimes he reacted emotionally to trifling incidents.

The emotional variability, the aponia, the absence of cognitive change, suggested the diagnosis of hysteria. The history of being idle at home for so long, the absence of desires for the future, the profound disability with only a few hypochondriacal symptoms suggested dementia præcox. The latter diagnosis was the correct one, for the patient became more and more apathetic, neglectful of his person, inclined to over-eat himself, and absolutely idle. But up to the time of his discharge intellectual change had not made

appreciable progress, and he remained capable of conversing on abstruse subjects, such as psychology, thus exemplifying in a marked manner the dissociation between the cognitive and conative elements. It is to be noted that he broke down after he had qualified in his profession. In point of fact, a number of patients appear to break down while trying to educate themselves to a higher level than their capacity justifies.

Dementia Præcox and the Compulsion Neurosis.—Now this neurosis varies from the recurring doubts about having left the gas on, common to all normal people, to a form so severe that the worrying thoughts nearly drive the patient to despair. It is these severe types which approach the psychoses most nearly. At first sight a psychosis characterised by apathy would seem to have little in common with a neurosis characterised by doubt and worry, but again it must be remembered that worry attends the feeling of initial disability in the early psychosis, and on the other hand, the extreme degree of doubt reached by the severe obsessional neurosis limits activity as successfully as the apathy of the dementia præcox. A severe obsessional neurotic, wrapped up in his obsessions, with perhaps a few compulsive ties, has only to lose insight to become a dementia præcox typical in all salient features.

CASE 3.—Female, aged 23. When 18 years old the patient lost energy and had to be dressed and taken about by her mother. After recovery, she remained well until twelve months before admission to hospital, when she complained of apathy, pains in the head, and sometimes thought that people were talking about her. The history of the previous attack sounded like a psychosis, but the recent symptoms appeared to be rather of the neurotic type, especially as she was worried by a number of compulsive acts. She felt compelled to shake her clothes before putting them on, and when she once started washing she felt unable to leave off. There was no loss of insight. The diagnosis at that time was doubtful; the insight she displayed, the anxiety about her disability, showed that if she were a psychotic, she was in an early stage, but the suspicious early history and the great loss of energy rather pointed to this probability than to a neurosis. As she remained in hospital it became obvious that a compulsion neurosis was not sufficient to account for the complete disability under which she laboured. While the obsessions remained about the same she gave evidence of deterioration in her slovenly appearance. Though she expressed anxiety about her condition, this contrasted strongly with her completely apathetic behaviour. Towards the end of her stay in hospital she began to experience fleeting hallucinations, but she always understood their subjective nature and showed no other evidence of cognitive change.

Dementia Præcox and the Anxiety Neurosis.—In this neurosis the patient shows the mental symptoms and some of the physical signs of an exophthalmic goitre, but usually without any marked enlargement of the thyroid. The feeling of anxiety may be present all the time, or acute attacks may intermit with periods of comparative calm. This would appear to be a condition the very antithesis of dementia præcox, but such is not always the case. The anxiety which the early dementia præcox shows may simulate the neurosis and occasion considerable doubt.

CASE 4.—Male, aged 27. The patient, a shy, seclusive youth, had served in the ranks during the war, though he had had a good education. Afterwards he had financial and domestic trouble, the latter because he became engaged to a girl of a lower social status. He became depressed, and made an half-hearted attempt to commit suicide. In hospital he showed a chronic anxiety state with occasional acute exacerbations, not related to any known cause. He made bizarre remarks—e.g., he felt that "his subconscious self was dominating his conscious," but showed no cognitive changes. His affective state was one of anxiety with consequent conative loss. Gradually he improved and took a rational view of his illness, and left hospital quite well.

Now several points in the history—the seclusiveness, his serving in the ranks, and the association with someone of a lower social status—rather pointed to the fact that he was an individual not quite capable of living in the sphere in which he had been born.

Consciously or unconsciously he was creating an environment adapted to his capabilities. As Case 2 sought to overcome his inferiority by educating himself to too high a standard, so this patient sought the opposite solution of deteriorating to a lower level. These facts, together with the attempt at suicide, suggested that the case might regress further to a typical dementia præcox condition. On the other hand, his symptoms in hospital were those of an acute anxiety state, and he steadily improved, becoming, as far as one could judge, as normal as he had ever been. He showed no residual changes, some sign of which one would expect if he were a dementia præcox with a remission. Thus the condition was a temporary breakdown which one may call an anxiety neurosis occurring in an unstable individual. He was still quite well some months after leaving hospital.

The Importance of Mental Symptoms.

From the description of the above cases it will be seen how difficult the diagnosis may be between a neurosis and dementia præcox. But the majority of cases fall more easily into one or other group, and if the general practitioner is on the look-out for the main features that have been described, he will be likely to diagnose this type of psychosis at a much earlier stage than he usually does at present.

The value of trying to classify and note the mental symptoms may itself be doubted, but this is important for several reasons. From the work of Sir Frederick Mott we know that a regressive change in the ovaries or testes and other organs is constantly found in the well-developed dementia præcox. Yet we have seen that the first signs of this serious condition are invariably mental, and only to be diagnosed from mental symptoms. Again, the doctor is often satisfied by finding some slight physical defect, entirely forgetting to investigate the general relation and reaction of the patient to his surroundings. While it is of the utmost importance that no physical illness should be overlooked yet it is worth while as well to consider these disorders from the psychological standpoint, to wonder why some patients react to an unsuitable environment with a neurosis, others with a psychosis, and to try to determine the correct relation of these conditions. The general practitioner can help to solve these and other problems, the solution of which will help to elucidate larger problems of human behaviour in general.

Summary.

(1) Dementia præcox is a common mental disorder in young adults. Following an insidious onset, it runs a prolonged course. The patient exhibits an inability to grapple with his environment, a consequent turning away from reality to live in a phantasy world of his own, with a progressive deterioration affecting primarily his emotions and ultimately his intellect in addition.

(2) The insidious onset causes considerable difficulty to an early diagnosis because the condition is liable to be mistaken for one of the common neuroses.

(3) The diagnosis between dementia præcox and these conditions is important because: (a) the different prognosis and treatment in the two cases; (b) the desirability of early investigation of dementia præcox; (c) the probability of extension of facilities for treating early cases in the near future.

(4) The diagnosis of dementia præcox mainly rests on: (a) considering carefully the history of the case with the development of the personality of the patient; (b) recognising the typical mental symptoms and physical signs, the most typical of which are the emotional apathy and loss of energy together with a poor circulation in the extremities.

I wish to thank the medical superintendent, Dr. Edward Mapother, for permission to publish this article.

PROPHYLAXIS AND THERAPY IN ANIMAL TUBERCULOSIS.

By H. SCHÜTZE, M.D.

(From the Lister Institute.)

NUMEROUS have been the attempts to produce immunity to or to cure tuberculosis in laboratory animals. Very few have been the successes reported, and those few apparently favourable results usually lack any subsequent confirmation or disproof. The reader is left with a single experiment, often of small extent and inadequately described, as a verification of the particular therapeutic theory.

Previous Experimental Work.

In the literature of the last 20 years have been found these accounts of experimental work on this question. Maffucci and di Vestea (1901) treated 124 guinea-pigs with a specific serum and prolonged the average life of these animals by eight days beyond that of the 31 controls.

Noguchi (1909) produced such immunity in four guinea-pigs by inoculating with T.B. dissolved in sodium oleate that one survived indefinitely, one died of intercurrent infection after 90 days, and two remained well for 50 days (subsequent history unknown), while four controls died in 22, 25, 34, and 36 days. Zeuner (1909) treated three guinea-pigs with a sodium oleate vaccine, and found that they lived one, one and a half, and three months longer than three untreated ones. Broll (1910) re-tested Zeuner's vaccine, and prolonged the life of his guinea-pigs as much as four weeks. Two immunised calves, killed ten weeks after infection, showed few post-mortem signs of tubercle, while the control died seven weeks after infection with massive tuberculosis.

Marxer (1911) continued the investigation of Zeuner's vaccine. In his first experiments the following results were obtained:—

(a) Fifteen control guinea-pigs infected with 1/100,000 mg. T.B. Death in 1-9 months; average = 6 months. Eighteen immunised guinea-pigs infected with 1/10,000 mg. T.B. Two alive after 11 months, remainder dead in 1-10 months; average = 7 months.

(b) Four control guinea-pigs infected with 1/10,000 mg. T.B. Death in 1-5½ months; average = 3½ months. Seven immunised guinea-pigs infected with 1/10,000 mg. T.B. Death in 5-10½ months; average = 7½ months. Four treated guinea-pigs infected with 1/10,000 mg. T.B. Death in 1½-6½ months; average = 3 months.

(c) Two control goats died in 1 month. Of five immunised goats one dies in 2 months, four are killed after 3 months, two showing little T.B. and two resembling the controls.

A later report states that subsequent experiments, in which six experimental and six control guinea-pigs were used, failed to confirm these favourable results, all animals dying in about the same time.

Möllers and Wolff (1913) used Zeuner's vaccine and failed to protect guinea-pigs or rabbits:—

Six control rabbits died after 2, 3, 3, 4, 4, and 4 months. Six treated rabbits died after 1, 1, 1, 1, 3, and 7 months. Five immunised rabbits died after 3, 3, 3½, and 6 months, one being killed after 9½ months and showing little T.B.

Von Ruck (1912) inoculated guinea-pigs with a vaccine consisting of the soluble proteins of the tubercle bacillus plus some of its fatty extractives—two controls died in 31 and 41 days with much tuberculosis, five immunised guinea-pigs were killed after 90 days and showed little disease. In another batch the control died in 23 days with much tuberculosis, five immunised animals were killed after eight weeks and showed less infection, nine immunised animals lived till the time of the report (? how many weeks). Cummings (1913) re-tested von Ruck's vaccine on 20 guinea-pigs and found that the ten controls died in 34-94 days, the average being 55, and that the immunised animals died in 32-154 days, the average

being 57. Brown (1919) also used von Ruck's vaccine but with a less virulent infecting strain. His eight controls were killed after 112 days and all showed signs of tuberculosis; the six treated animals killed at the same time showed none.

Frugoni and Grixoni (1909) treated rabbits (? number) with thyroid extract and found they live longer (? how much) than the untreated. Ruppel and Rickmann (1910) claimed to have prolonged life in guinea-pigs for four months by means of immunisation (? details) with a specific serum. Of 14 guinea-pigs treated with a T.B. vaccine sensitised with this serum, ten survived for at least five and a half months and four died after one and a half, one and three-quarters, four and a half, and five months with little or no tuberculosis, whereas the controls (? number) all died in five to six weeks with marked tuberculous disease. Linden (1920) influenced the course of T.B. in guinea-pigs and rabbits favourably by means of copper salts.

Momose (1913) used a vaccine of T.B. treated with 10 per cent. NaOH and extracted with chloroform.

(a) Of five control guinea-pigs infected with 1/1000 mg. all die in 6-12 weeks. Of seven immunised guinea-pigs infected with 1/1000 mg. none die in 12 weeks. Of eight immunised guinea-pigs infected with 1/100 mg. three die in 12 weeks. T.B. lesions less as a rule in the treated than the untreated.

(b) Two control guinea-pigs die in 10 and 12 weeks, showing marked T.B. Of five treated guinea-pigs one dies in 17 weeks and four are killed after 24 weeks and show either no or slight T.B.

(c) Of ten control guinea-pigs six die in 4-14 weeks and four are killed after 10 and 16 weeks, all showing marked T.B. Of ten treated guinea-pigs three die in 7, 8, and 10 weeks, and seven are killed after 10 and 16 weeks, some showing no T.B., others slight T.B.

Rappin (1913) gave a vaccine (? living) of T.B. treated with specific serum and protected guinea-pigs (few details). Ostromushuski (1916) claimed to have protected guinea-pigs and influenced the course of the disease favourably by injecting copper gynocardate. Laitinen (1921) found that 20 guinea-pigs treated with calcium phosphate live one month longer than 30 treated with calcium hydroxide. Seiffert (1924) injected guinea-pigs with T.B. dissolved in NaOH—two controls lived 65 and 70 days, two treated eight days after infection live 64 and 68 days, two treated synchronously with infection live 166 and 170 days. Droussin (1921) declared that a vaccine treated with sodium fluorate and a specific serum (? nature) invariably immunised animals (no details). Serra (1921) raised the resistance of rabbits by feeding with the active principle of the liver (no details). Perrin and Remy (1921) treated four guinea-pigs with extract of nettles, and found that they lived for 24, 61, 63, and 75 days as compared with the 53 and 56 days of two untreated ones. Kahle (1921) considered that silicic acid induced a more chronic type of infection in guinea-pigs with a tendency to healing. Frank (1923) did not confirm the favourable effect of silicic acid. Culpepper and Ableson (1921) treated 12 guinea-pigs with sodium chaulmoograte, with one spontaneous death in 37 days (of 12 controls 11 die in 28-78 days), the remaining animals being killed off one for each death among the controls. Treated animals have improved weights and less advanced T.B. as compared with the untreated ones.

Dreyer (1923) treated four guinea-pigs, 28-39 weeks after infection, with a vaccine extracted with formalin and acetone (diaplyte vaccine): one died 11 weeks after commencement of treatment with signs of slight T.B., the three remaining animals were alive 16-20 weeks after treatment was begun (no controls). He also treated three rabbits five weeks after infection with a bovine strain and found their weights increased, whereas that of the one control remained stationary. Also inspection of the ulcer and nodule at the site of inoculation was regarded as evidence in favour of a beneficial influence exerted by the vaccine.

Boquet and Negre (1923) treated 50 guinea-pigs in three groups with a methylic extract of T.B.—death occurred after averages of 137, 140, and 90 days as compared with the 98, 97, and 90 days of the 18 animals in the three groups of controls. Treated rabbits die, four in 97 days, four in 89 days, as compared with two controls in 63 days. Of eight rabbits given a minute dose the two controls die after three months with massive T.B., and of the six treated animals five die after five and a half months with less than the usual signs of infection and one is killed after nine months showing but a few scars. Raw (1924) inoculated prophylactically with killed human T.B. of attenuated virulence. While five control rabbits died of infection with an attenuated bovine virus within four months, four of the five inoculated animals are still alive after ten months. Row (1924) injecting a vaccine of autolysed T.B. extracted with chloroform into guinea-pigs infected with T.B., kept five out of six alive and well—no T.B. seen on killing—for six months and more. The five controls all died in three to ten weeks.

A list of experiments such as this, neither confirmed nor definitely disproved, is very unsatisfactory, and gives clinicians no indication as to the direction in which they are to seek a likely therapy. To come to any conclusion as to the respective merits of these varied systems of prophylaxis and therapy is difficult, and the paucity of animals under observation often renders it impossible; failure to repeat results when the same type of antigen is used on different occasions is frequent, a spurious protection having sometimes, not impossibly, been obtained by the tubercle vaccine not being absolutely dead, for a living inoculum has been shown by Calmette (1924) and others to be capable of inhibiting a superimposed infection. It is important, therefore, that where attention has been widely drawn to a new remedy, the evidence which animal experiment can afford should be multiplied, and with this in mind the following series of inoculations was performed.

Therapeutic Experiment with Dreyer's Diaplyte Vaccine.

The experiment here described was carried out on the lines of the one reported by Prof. Dreyer. The animals employed were guinea-pigs fed on the regulation diet of oats, hay, and greenstuff. The infecting organism was, in the case of one batch of 18 animals, a human T.B. of medium virulence, "Lyons." The other batch of 18 received an attenuated bovine strain, "H 159 (b)," kindly supplied by Dr. A. S. Griffith. A tenth of a milligramme was inoculated subcutaneously into the thigh of each guinea-pig. Five weeks later, treatment with Dreyer diaplyte vaccine was begun. This vaccine was prepared with a six weeks' old glycerine-broth culture of a bovine strain "B 4." After one repetition of the extraction with formalin and acetone, defatting was complete. A Ziehl-Neelsen film counter-stained with methylene-blue revealed no acid-fast or other recognisable bacteria; one counter-stained with strong carbol-fuchsin showed numerous more or less faintly staining bacilli and their fragments. The vaccine was diluted to the prescribed strength of $\frac{1}{5}$ mg. per c.cm. and given subcutaneously into the flanks of half the guinea-pigs, nine in each batch. The dosage, based on that used by Dreyer, varied from $\frac{1}{2}$ to 1 c.cm., and was given at intervals of one to four weeks, the actual dates and doses being Oct. 19th, $\frac{1}{2}$ c.cm.; Oct. 26th, $\frac{1}{2}$ c.cm.; Nov. 5th, $\frac{1}{2}$ c.cm.; Nov. 12th, 1 c.cm.; Nov. 22nd, 1 c.cm.; Nov. 30th, 1 c.cm.; Dec. 12th, 1 c.cm.; Dec. 20th, 1 c.cm.; Jan. 7th, 1 c.cm.; Feb. 6th, $\frac{1}{2}$ c.cm. The daily weight curves indicate that the animals tolerate the inoculations well. No fall in weight could be related to the treatment and, indeed, throughout the experiment the curves of the treated and untreated guinea-pigs ran very similar courses. The dates of death are shown in the table given below.

Post mortem, similar lesions were seen in both the treated and the untreated—abscesses at the site of inoculation, caseating glands, enlarged spleens, necrotic

and caseating, livers, large and mottled; the lungs might be crepitant or hepatised, and in the case of the animals infected with the human strain, always studded with tubercles, in those infected with the bovine strain, the lungs were generally free from macroscopic signs of tuberculosis.

Guinea-pigs Infected with B. tuberculosis (Half the Number being subsequently Treated with Diaplyte Vaccine).

	Number of days after infection at which death occurred.	Average.
1. Infecting strain "Lyons," human T.B.		
Treated ..	48, 54, 73, 100, 105, 111, 115, 123, 164 ..	99
Untreated .	85, 92, 103, 115, 124, 142, 152, 185, 187 ..	113
2. Infecting strain "H 159 (b)," attenuated bovine T.B.		
Treated ..	112, 117, 120, 135, 150, 153, 155, 172, 213 ..	147
Untreated .	122, 163, 167, 171, 189, 213, 215, 226, 342 ..	201

Similar results have been obtained by Kettle and Caulfield, working independently, and using Dreyer's antigen: Kettle's (1924) ten control guinea-pigs lived on the average 78 days, while the treated ones lived 53 days; in another batch the eight guinea-pigs, given prophylactic as well as therapeutic doses, also lived, if anything, a shorter time than the untreated controls. The fibrosis which Dreyer saw in the lesions of his guinea-pigs and regarded as evidence of a tendency to healing, Kettle was able to demonstrate in his controls as well. And indeed it has been an established fact, since the Royal Commission on Tuberculosis (1911), that in guinea-pigs which live more than 100 days after infection with human T.B. fibroid and calcareous changes are frequent.

Caulfield's (1924) four control guinea-pigs died in 6-15 weeks, average = 10½ weeks; his six treated guinea-pigs died in 7-2 weeks, average = 10 weeks; his four guinea-pigs given prophylactic as well as therapeutic inoculations died in 9-24 weeks, average = 13½ weeks.

The criteria of weight curves, survival rates, and macroscopic post-mortem appearances being applied to the experiment detailed above, no evidence of a favourable influence exerted by this diaplyte vaccine—employed curatively and in the doses recommended—on the course of tuberculosis in guinea-pigs has been observed.

Clinical and Laboratory Notes.

STRICTURE OF ANAL CANAL FOLLOWING IMPROPER TREATMENT.

By WILMOT ADAMS, F.R.C.S. ENG.,

SENIOR SURGEON, STRAITS SETTLEMENTS MEDICAL SERVICE.

I VENTURE to think this case may be of interest in bringing out (1) the disastrous results of unskilled treatment, and (2) the efficacy of local anaesthesia in what was practically a Whitehead's operation.

A Chinese female, aged 38, was admitted to the General Hospital, Penang, on Jan. 23rd, 1923, suffering from anal stricture.

History.—About four months previously she consulted a Chinese medicine man on account of bleeding piles. He guaranteed a cure, and his procedure was as follows. She was heavily dosed with opium and a suppository containing lime was put into the rectum and kept there by pad and strapping for four days. For the first month after this she was fairly comfortable and the optimistic quack assured her she was cured. She then began to have difficulty in the passage of motions and in the control thereof.

Condition on Admission.—The anal canal consisted of a mass of fibrous tissue extending upwards for 1 inch, the lumen of which admitted a No. 6 English catheter. She was completely incontinent and was suffering from a very marked degree of intestinal intoxication.

Operation was performed under local anaesthesia of ½ per cent. novocaine preceded by morphia and hyoscine. The stricture was removed en masse in exactly the same way as the pile-bearing area is removed in Whitehead's operation, and the cut edge of the healthy mucosa above stitched to the skin. This procedure was practically bloodless and anaesthesia was perfect, in fact the patient was sleeping during the latter part of the operation.

Recovery was uneventful. She had no incontinence even during the first few days, and left hospital in the third week with no suspicion of any further stricture developing.

I am indebted to Dr. A. L. Hoops, principal civil medical officer, Straits Settlements, for permission to publish this case.

LARGE UTERINE FIBROID REMOVED DURING PREGNANCY.

By W. WORGER, M.R.C.S.,

SURGEON TO BURNHAM-ON-SEA WAR MEMORIAL HOSPITAL.

THE following case of removal of a large fibroid from a three-months pregnant uterus without interruption of pregnancy is of considerable interest:—

A patient, Mrs. K., was admitted into the Burnham-on-Sea War Memorial Hospital under my care on March 1st, 1924, suffering from a fibroid tumour of the uterus. Seven months previously she had first noticed an abdominal swelling, but it did not cause her any inconvenience. A month ago she had an attack of acute abdominal pain, for which she consulted my partner, who diagnosed a fibroid. Menstruation had been regular until three months ago. She was under her doctor's observation for a month, during which there was no definite increase in size in uterus or abdominal measurements. By examination on admission I found that she had a large abdominal tumour, reaching as high as the umbilicus and attached to the uterus, solid to touch, and showing no contractile movements. Uterus slightly enlarged. On operating I found a large fibroid attached to the fundus of the uterus, there being also a smaller tumour in the posterior wall of the uterus in the lower segment. The uterus was slightly enlarged and I could feel that it contained a foetus. I decided to remove the large fibroid and preserve the uterus, and this I did without a great loss of blood. I also shelled out the smaller tumour, and closed the abdominal opening. The tumour weighed 4 pounds.

The patient made an uneventful recovery and was discharged from hospital on March 24th, 1924. She was readmitted on Sept. 2nd, 1924, and gave birth to a 6 lb. 14 oz. live male child.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF EPIDEMIOLOGY, COMPARATIVE MEDICINE, AND DISEASES OF CHILDREN.

THE adjourned meeting of this Section (see THE LANCET, Feb. 14th) for the discussion of the

CONTROL OF TUBERCULOSIS AND THE MILK-SUPPLY was held on March 2nd, Dr. JOHN MCVAIL, President of the Section of Epidemiology, being in the chair.

Dr. M. J. ROWLANDS spoke of his practical experience in pig-farming, and ascribed the liability of cattle to tuberculous infection to the two factors of bad feeding and overwork.

The Vitamin Factor.

Nowadays, he said, there was practically no vitamin-content in the diet of dairy cows, the whole of the germ was taken out, and an animal that was intended by Nature to produce sufficient milk for one calf at a time when natural vitamin-rich foods were prevalent was made to yield from one to two thousand gallons per annum, working for eight or ten months without rest. Such a drain on the fat and protein must result in a low immunity. Among his pigs tuberculosis had been very prevalent, even under the most scrupulous hygiene, but he had completely eradicated it in one year by attention to the vitamin-content of the diet, without any methods of isolation or disinfection. Almost every prize animal in a certain famous herd of cattle gave positive results with the tuberculin test, while the other members, not fed on artificial foods, showed a far smaller proportion of reactors. The rarity of tuberculosis in sheep, horses, and bullocks was to be ascribed to their more natural life. In collaboration with Dr. Chalmers Watson, of Edinburgh University, he had found that pigs fed on a vitamin-rich diet passed one-third less protein in their stools than those fed on the usual substances. He had found it important to supply animal protein, as there was a conversion loss of 25 per cent. on vegetable protein. Slaughter of all tuberculous cows in the country would give immunity for two years only; it was not possible to pull down all the cowsheds and they were full of tuberculosis; sunlight, cleanliness, segregation, and disinfection were good measures, but would not eradicate the disease. The only satisfactory method was to increase the natural immunity of the animals by providing a diet rich in carbohydrate, protein, mineral salts, and vitamins.

Pathogenicity of the Bovine Bacillus.

Dr. A. S. GRIFFITHS, speaking from the point of view of the bacteriologist, showed a number of charts illustrating the work of the bovine bacillus in human pathology. The Royal Commission of 1911 had disproved Koch's statement that this form of tuberculosis was without serious menace to man, and further investigations had served to confirm their findings. In gland tuberculosis the bovine bacillus had been found in 85 per cent. of cases under 5 years of age; in 18.2 per cent. of adults. In bone and joint tuberculosis the percentages were 30.2 and 5.9; in scrofuloderma 58.3 and 7.7; in lupus 66 and 17.6. There was evidence of a slight increase in the incidence of bovine infection since 1910. The animal form was responsible for 19 per cent. of genito-urinary tuberculosis of all ages, 1.1 per cent. of pulmonary disease (found in three cases only), and 66.6 per cent. of meningitis, taken from the cerebro-spinal fluid during life. Thus some 80 per cent. of the infections that had entered by the alimentary tract were due to the bovine bacillus. These results had served to disprove Calmette's assertion that phthisis entered via the abdominal glands, and there was no evidence

that the bovine form could be converted into the human. There was no clinical distinction between surgical cases of tuberculosis in laboratory animals produced by the two varieties; and such evidence as was available pointed to a slightly higher degree of intrinsic virulence on the part of the bovine. The obvious corollary of such findings was the urgent necessity for removing tubercle bacilli from milk.

Mr. G. P. MALE expressed the disappointment experienced by certain of the veterinarians at the previous discussion on hearing the promulgation of such counsels of despair as pasteurisation and the immunising value of a few live bacilli in the milk drunk. He believed there were certain hopeful features in the situation, such as the increase in the number of farms supplying certified and grade A milk, and the reduction of the proportion of reactors in the herds from 50 per cent. 20 years ago to less than 5 per cent. at the present time. He referred to the remarkable improvement in the hygienic conditions of housing which resulted from the work of Dr. Stenhouse Williams at Reading, where it had been proved that clean milk could be produced in old buildings without material alteration, and the farmers had been satisfied that the production of such milk and the eradication of tuberculosis from their herds was a sound commercial proposition. He admitted the force of the two objections raised—viz., the increase of cost to the consumer and the danger of distributing reactors to other centres, but thought there was no reason why grade A milk could not become the staple supply of the country if only the doctors would support it. This could be sold at a profit by the addition of 1d. per quart to the retail price. The dissemination of reactors, also, only resulted in their becoming collected in the herds of owners who were not anxious to provide tested milk, and such herds would become known to the medical officer of the district. Mr. Male emphatically urged the reintroduction of the Tuberculosis Order; he had helped to work it during the short period it was in force and could speak to its efficacy. Its cost might be some £80,000 per annum, but the cost of sanatorium treatment for children infected with bovine tuberculosis would go a long way towards meeting that sum. In the 12 months of the Order's life over 1500 milk samples containing tubercle bacilli had been traced to their source and the animals slaughtered. There must be close co-operation between the medical officers of health and the veterinary inspectors so as to encourage in every way the production of certified or grade A milk, with regular inspection of herds once every three months.

The Farmer's Point of View.

Dr. STENHOUSE WILLIAMS spoke strongly of the distress it had caused him to hear the worst specimen of farmer held up to the meeting as a type. The Berkshire farmers had taken immense trouble to render their cows perfectly clean. The cows were brought in, washed thoroughly, and the workers then changed their coats, washed themselves and, seated on a clean stool, milked into covered sterilised buckets, which were subsequently placed into sterilised containers over sterilised coolers, and thence into a sterilised ten-gallon churn which was sealed, marked, and unventilated. The retailer in his turn put the milk into a sterilised receiver, and thence into a sterilised bottle, capped and sealed it, and it was thus delivered, fresh and clean, to the consumer's house for 1d. per quart extra. Dr. Stenhouse Williams quoted one such instance of a farmer who had cleared his herds at considerable financial loss, and when he then offered his milk to the local hospital at the ordinary rate his contract was refused. The dealers also refused his milk, and he had to start a dairy business at his own expense in order to get his milk on the market. Within two years it formed one-sixth of the total supply of the town. Such a story was a reproach to the medical profession, and one reason why the consumption of grade A milk was not widespread was that the doctors failed to support it. The alternative

was pasteurisation, as in New York, where it was beginning to be questioned whether the large amount of latent scurvy might not have some connexion with the high percentage of pasteurised milk. In his opinion the far better way was to support the idea of fresh, clean, tuberculin-tested grade A milk, not forgetting that this country could boast the most intelligent farmers in the world.

Importance of Expert Inspection.

Sir LAYTON BLENKINSOP agreed that the veterinarians had been much disappointed at the apparent satisfaction with pasteurisation; he had no doubt that hygienic conditions and the placing of herds under the control of practised veterinary surgeons would result in the eradication of the disease. The best help to the farmer was to give him the advice of competent clinical experience, and no one was keener to follow sound advice than the British farmer. His experience with glanders and mallein-testing in the army had led him to believe that the first essential was recognition of the symptoms of the disease. He agreed as to the necessity for urging the reintroduction of the Tuberculosis Order.

Dr. D. NABARRO said he had no doubt that herds could be freed and kept free for a time, but this freeing of them resulted in a lowering of their immunity; he was not quite convinced of the desirability of so doing, nor was he sure that small doses in milk did not confer a valuable immunity. Of course, cases of gross udder disease or advanced tuberculosis must be slaughtered, but to destroy all reactors was going too far. He believed in the mutability of the bacillus and that the rarity of bovine infection in adults was to be accounted for by its alteration after long sojourn in the human body. He referred to the work of Collie, Beattie, and others on acid-fast bacilli which could be modified by passing through guinea-pigs into bacilli having all the characteristics of tubercle. He urged that these important results should be further investigated, and that such unsolved problems should be put to the test before the country embarked on a wholesale slaughtering of cattle.

Dr. NATHAN RAW expressed it as his opinion that practically all surgical tuberculosis was bovine and bore no relation to pulmonary disease. Some 10,000 children were lost annually through the work of this bacillus and some 5 per cent. of the million dairy cows in the country were suffering from tuberculous disease of the udder. Slaughter was no solution; the most hopeful method of attack was to immunise the calves as they were born. Until this process could be completed pasteurisation or boiling of uncertified milk should be made universal. He had never seen any ill-effects from the use of pasteurised milk. He urged that the Tuberculosis Order should be re-enforced, remarking that Parliament was anxious to take any steps that would ensure a pure milk-supply for the country. The Reading testing centre was a model for the country, but it would be some time before such a standard could be made universal.

Dr. H. SCURFIELD said that the towns which had had milk clauses in force showed no evidence of any reduction of the tuberculosis incidence. He referred to the insidious way in which the infection creeps in to free herds and asked how this was to be explained. Was it due to the fact that a cow might have an early infection which did not give a positive reaction, or was it due to the doping of animals with tuberculin? It was known that a tuberculin test rendered the animal negative to subsequent tests for a certain time. He urged the standardisation of tuberculin and the restriction of testing to competent veterinary surgeons, every cow tested to be marked in some way. He most cordially agreed with the importance of the vitamin diet, and the necessity for spreading institutes such as that of Reading over all the country. In his experience, if sufficient care were taken in following up a sample of tuberculous milk swiftly an infected udder was always found to account for it. He agreed that veterinary surgeons of clinical aptitude were necessary.

Prof. F. T. HOBDAV spoke of the seriousness of this possibility of doping cattle; any unscrupulous dealer had only to get a syringe and some tuberculin to render his cows negative to any test. There should be some control. He believed in the immunisation methods and thought they were well on the way to a successful issue. The country could be free of tuberculous cattle in 20 years by this method.

Dr. HENRY GRAY believed in total eradication as the only way of getting rid of the disease. It was not for the medical profession to consider costs and adopt tinkering methods; it was for them to say what ought to be done to prevent tuberculosis in children and for the public to determine whether it would pay the price or not. Neither housing nor vitamins would settle the difficulty; there was only one cause of the condition and that was infection.

Sir WILLIAM HAMER spoke in favour of feeding and housing methods, having reference to the remarkable results achieved by these measures among human beings.

Sir LEONARD ROGERS pointed out that all milk in India had to be boiled, and the children did very well on it. In his opinion pasteurisation was the best method until the disease could be eradicated in cattle, and grade A milk made the supply of every home.

The PRESIDENT, in concluding a good discussion, spoke of its vast importance and great interest. He deprecated any suggestion as to the existence of two sides in this matter; there was no contradiction; pasteurisation was merely a temporary precaution while the work of eradication was being completed.

A resolution calling upon the Council of the Society to urge upon the Government the immediate re-enforcement of the Tuberculosis Order was carried unanimously.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE.

Preventive Control of Diphtheria.

At a meeting of this Section held on Feb. 26th, with Dr. JOHN MCVAIL, the President, in the chair, Dr. WILLIAM ROBERTSON, medical officer of health, Edinburgh, read a paper on the above subject. Having remarked that the usual measures with regard to diphtheria had rather the appearance of locking the stable door after the steed was stolen and referred to the anxiety given to all public health departments by the presence of carriers, Dr. Robertson described the methods adopted in Edinburgh to secure a systematic immunisation of the school population. Explanatory leaflets and consent forms were distributed to all scholars under the age of 10 years. Parents were asked to consent to a preliminary Schick testing, then, if necessary, three preventive inoculations and a final Schick testing. In the better class schools as many as 86 per cent. of the parents consented, but in the poorer districts the percentage sometimes fell to 40; when the percentage of consents was 50 or less a second appeal sometimes brought the figure up to 70. When skilled workers were employed and the coöperation of teachers secured, it was possible to make the tests at the rate of 100 to 120 an hour. It was found, as elsewhere, that the proportion of positive reactors was much higher in the better social strata. It also appeared that passing through an attack of diphtheria did not confer a lasting immunity, as judged from the Schick reaction. Experience had shown that in young children, aged 2-5, immunisation could properly be done without a preliminary Schick test. From the preventive point of view, it would be expedient to concentrate attention upon children of pre-school age. It was essential that the method should be applied only by trained persons.

Sir WILLIAM HAMER wished to have more information as to the results, in particular with regard to the New York experience.—Dr. O'BRIEN remarked that the mixture used in Edinburgh was, so far as guinea-pigs were concerned, much less toxic than that employed in New York. He referred to improvements

already effected in the production of antitoxin and looked forward to yet greater improvements.—Dr. S. MONCKTON COPEMAN remarked that in England, so far, only schools used by the wealthier classes and Poor-law schools had made much use of the method. The higher percentage of immunes in the poorer classes was apparently due to more frequent normal exposure, because, in a higher grade school in Norfolk, where there was definite exposure to risk, the proportion of negative reactors had been found to be very large.—Sir GEORGE BUCHANAN hoped that it would be possible to ascertain whether the subsequent attack-rate of the immunised children in New York was lower than that of those not immunised. He congratulated Dr. Robertson on this piece of work and inquired whether reactions on inoculation had given rise to trouble, whether it had been found necessary to warn parents.—Dr. MAJOR GREENWOOD deprecated any premature attempt to "prove" the efficacy of the process by statistics. At present the method should be regarded as a reasonable one, one to be accepted by intelligent people; in time a statistical assessment would be possible.—Dr. RANDALL asked whether immunisation had reduced the number of carriers.—Dr. TROTTER thought that the public health services in Scotland had a considerable advantage over those in England both by virtue of having somewhat greater powers and of being in closer contact with the people.—Dr. HUME thought that the small size of Edinburgh compared with London and the prestige of the medical school explained the greater willingness of the population to follow medical advice.—Dr. SCOTT thought that the variation of the proportion of natural immunes was one of the most interesting problems from the standpoint of immunology; the explanation by subinfection was not really very satisfying.—Dr. FORBES said that Edinburgh stood alone in dealing with the school population. In the south the method had been practically confined to large institutions.—Dr. REGINALD DUDFIELD remarked that, as in the matter of tuberculosis dispensaries, Edinburgh was doing pioneer work. He inquired as to the verification of a history of previous diphtheria and also asked for information on the subject of carriers.—The PRESIDENT tendered his congratulations and those of the Section to Dr. Robertson. It was difficult not to be envious of New York. Probably the medical profession required more education, and he thought that Dr. Hume's remarks on the medical atmosphere of Edinburgh were highly relevant. He also deprecated any premature statistical "proofs."

Dr. ROBERTSON, in his reply, said that it was too early to give statistical results, but in a school which had formerly given much trouble no cases had occurred amongst the immunised. It had not been found necessary to issue warnings as to reactions. There were some reactions at the age of 10–11, but they were confined to slight rises of temperature and local induration. The method was not serviceable in the elimination of carriers. Carriers did not react. Histories of alleged diphtheria were verified from notification records.

LONDON ASSOCIATION OF MEDICAL WOMEN'S FEDERATION.

A MEETING of this Association was held on Feb. 10th, Miss M. CHADBURN being in the chair.

Miss FRANCES IVENS read a paper on the

Prevention of Puerperal Morbidity and Mortality.

She had long been interested in this subject from a gynaecological standpoint, and had welcomed an opportunity to make observations from the obstetrical side to determine to what extent the morbidity, immediate and remote, following childbirth was preventable. Five years ago, with this object in view, she undertook, at the invitation of Dr. E. W. Hope,

then medical officer of health of Liverpool, the supervision of the new maternity home which was started on his initiative. The home could only take in 14 patients, but since its opening in 1920 1000 admissions had taken place. As far as possible, Miss Ivens saw every case before admission and made an examination. A specimen of any abnormal discharge was sent to the city bacteriologist for report. Cases of active syphilis or gonorrhoea were referred to a special institution, and cases of albuminuria, cardiac disease, hyperemesis, &c., were admitted for antenatal care. Cases requiring Caesarean section were sent on to the Stanley or Maternity Hospital. At this home before any internal examination is made the vulva is shaved and washed with lysol solution. In emergency cases tincture of iodine is also used. During labour all those concerned with the case wear sterilised overalls and boiled gloves. The matron or sister conducts all normal cases with the assistance of the pupil midwives, who are all trained nurses. Any perineal rupture is repaired at the earliest possible moment with silkworm-gut. The wound is kept dry and is touched once daily with tincture of iodine. During the puerperium the vulva is swabbed four-hourly during the day with lysol solution and a large sterile pad applied. The patient is encouraged to lie on her side for part of every day and to sleep in an exaggerated Sims position, which is not uncomfortable. Anteversion of the uterus is thus encouraged. In cases of ruptured perineum micturition is performed on the hands and knees so that the wound is not soiled and catheterisation is avoided. Of 1000 patients admitted 206 were pre-maternity cases and 679 were maternity cases, of which 390 were primiparae and 289 multiparae; 118 were postnatal cases. Miss Ivens said that there had been no maternal mortality among these cases and no maternal morbidity according to C.M.B. Rules among the cases delivered in the home.

Miss Ivens proceeded to classify the cases. Contracted pelvis occurred in 130 cases, the high percentage being probably due to the fact that a proportion of the cases were referred from outside clinics, doctors, and midwives for special observation and care. Of the total number of maternity cases (679), natural delivery took place in 601—88 per cent. Among the complications met with were post-partum hæmorrhage (three severe and two slight), adherent placenta, perineal tears, fibro-myomata, twin births (eight pairs), unreduced occipito-posterior position, placenta prævia (eight cases), prolapse of cord, pelvic presentations (25 cases), face presentations (two), eclampsia (one as an emergency). Induction of premature labour was employed in 48 cases. Delivery by forceps was effected in 30 cases and 29 patients required Caesarean section. As to the infants, 39 were stillborn or died in the first ten days, of which 22 were premature; 687 children were born and 648 remained alive. Miss Ivens described 11 cases where there had been some morbidity. Full details of this investigation would shortly be published.

She recognised that it was unwise to draw definite conclusions from such a small number of cases, but she was inclined to believe that the results led to the following among other conclusions: That latent or pre-existing infection is responsible for a considerable percentage of cases of puerperal sepsis; that the organism may not infrequently be isolated from the urine during pregnancy; that intermittent albuminuria during pregnancy is an indication for bacteriological examination of the urine; that cases should be removed from unsuitable surroundings and accommodation in homes should be sufficiently ample for patients to be admitted a day or two before labour is anticipated; that rigidly aseptic technique is important; that well-trained midwives can deliver a very high percentage of maternity cases if efficient antenatal care has been given and if skilled medical help and, if necessary, institutional treatment can be obtained when required; that in view of the need for study of the origin and character of the infecting organism in cases of fulminating puerperal fever

such cases should be placed at the earliest possible moment under the care of an obstetrical specialist and a bacteriologist.

Discussion.

Dr. VIOLET RUSSELL spoke of the technique adopted in private cases. She emphasised the need for efficient sterilisation of (1) the surgeon's hands, (2) the patient's body; she held that gloves should always be used and did not consider that swabbing was much good. The vulva, the vagina, and cervix should be generously painted with tincture of iodine.

Dr. E. PHELPS spoke of the gap between conditions in the practice of specialists and those which obtained in, for example, the East-End of London.

Lady BARRETT said she was specially interested in the cases described by Miss Ivens where there was a pre-existing focus of infection. She was drifting away from the theory that wound infection was the most important cause of puerperium sepsis. The factors which had to be thought of were (1) the focus in the mother, (2) low resistance in the mother, and (3) infection by attendant. A mask might be a more important preventive than a gown. She was not certain that the banished theory of air infection would not have to be revived in view of certain recent experiences of her own.

Miss I. MANN asked what routine prophylaxis was adopted by Miss Ivens against ophthalmia neonatorum.

Dr. GLADYS SANDES asked whether the cases of gonorrhœa admitted to the home had had any previous treatment.

Miss IVENS briefly replied. Boracic lotion only was used as a routine measure for the infant's eyes and argyrol in suspicious cases. Cases known to have gonorrhœa were not admitted, therefore most of the admitted cases had not been treated.

New Inventions.

OUTLINE DIAGRAM OF THE LARYNX: RUBBER STAMP.

THE conventional diagram of the larynx has descended to us from the early days when the chief interest of a laryngeal case was "to see the cords" and anything growing thereon. This diagram was

particularly unsatisfactory for displaying the interarytenoid region which, with the neighbouring area above each vocal process, is the most frequent site for the deposit of tubercle. The outline drawing here figured is, of course, semi-diagrammatic

and has been made by Dr. W. H. Smurthwaite in accordance with my design. It is impossible in the larynx to view both the interarytenoid region and the laryngeal surface of the epiglottis at one and the same time. Still, this conventional outline will enable laryngologists to indicate changes in any part of the larynx including the posterior wall, both sides of the ary-epiglottic folds, the sinus pyriformis, and the post-cricoid region—all of which are inadequately represented in the usual diagram of the larynx.

The design, as a rubber stamp, has been put on the market by Messrs. Mayer and Phelps, 58, New Cavendish-street, London, W. 1.

Wimpole-street, W.

STCLAIR THOMSON.

Reviews and Notices of Books.

LEPROSY.

By Sir LEONARD ROGERS, C.I.E., M.D., F.R.C.P., F.R.C.S., F.R.S., I.M.S. (ret.), Physician and Lecturer, London School of Tropical Medicine; late Professor of Pathology, Calcutta Medical College; and ERNEST MUIR, M.D., F.R.C.S. Edin., Research Worker in Leprosy at the School of Tropical Medicine and Hygiene, Calcutta. Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd. 1925. Pp. 301. 12s. 6d.

THE appearance of this book marks a definite advance in our knowledge of an ancient and loathsome disease. The subject-matter shows evidence of a great amount of research, historical and statistical, the two being woven into one continuous story. The first section deals with the history and distribution of leprosy; it gives the ancient records, and describes the spread throughout Europe, the subsequent decline, and later the invasion of the Pacific islands. The distribution of leprosy is a subject to which Sir Leonard Rogers has devoted much study, so that his recent views on the incidence in relation to rainfall and latitude will receive careful consideration. The second section of the book concerns epidemiology and communicability, many instances being given from the literature in which the source of infection has been definitely ascertained. The third section details the various prophylactic measures adopted in historical and recent times, and will be read with special interest as affording an indication of the value of strict and compulsory segregation in stamping out leprosy.

The clinical section is illustrated with a series of excellent photographs, and constitutes a valuable contribution to the symptomatology of leprosy. But it is to the last section that the majority of readers will turn most eagerly, and here they will find a moderate and maturely considered opinion on the results of treatment already obtained. Research in methods of administering the oils of chaulmoogra has culminated in the injection of the esters of hydnocarpus oil by infiltration of the subcutaneous tissues. Stress is wisely laid upon the importance of selecting suitable cases for treatment, and the desirability of warning the patient from the outset that care must be protracted, and that the chances of final recovery depend upon the energy and persistence with which he carries out his part. Some of the photographs which illustrate the effects of specific treatment are impressive.

This book is the outcome of painstaking labour. The search through the literature necessary to compile a record of 700 cases in which the probable source of infection was traced, as tabulated in Table IX., must have consumed an immense amount of time. The style is clear and the teaching is free from personal bias. It is likely that it will remain the standard work on this subject for many years to come.

SURGERY.

A Manual of Surgery. ("Rose and Carless.") Eleventh edit. By ALBERT CARLESS, C.B.E., M.B., M.S. Lond., F.R.C.S., Emeritus Professor of Surgery, King's College, London; Consulting Surgeon, King's College Hospital. Assisted by CECIL P. G. WAKELEY, F.R.C.S., Assistant Surgeon and Lecturer in Clinical Surgery, King's College Hospital. London: Baillière, Tindall and Cox. 1924. Pp. 1570. With a Radiographic Supplement. 30s.

THAT this old-established manual of surgery continues to fill a definite requirement of practitioners and students is shown by the frequent calls for a new edition. In the latest revision Mr. Carless has been

assisted by Mr. C. P. G. Wakeley. The work seems to have been done as carefully as heretofore, recent changes in surgical opinion and practice being recorded with the same discrimination and balance. By giving just the right amount of information on any particular subject the authors have been able to accomplish the almost impossible task of compressing modern surgical teaching into a single volume of moderate compass. "Rose and Carless" seems to possess the secret of perpetual rejuvenation.

Handbook of Operative Surgery. Fourth edition. By Sir WILLIAM I. DE C. WHEELER, B.A., M.D., F.R.C.S.I., F.A.C.S., Surgeon to Mercer's Hospital and the National Children's Hospital, Dublin. London: Baillière, Tindall and Cox. 1925. Pp. 441. 15s.

In this, the fourth, edition of Sir William Wheeler's well-known handbook a thorough revision has taken place and a number of alterations have been made. Obsolete operations have been omitted and new matter dealt with. The book has attractive features and has a personal note not always seen in small text-books of its kind; a number of useful practical hints are scattered through the descriptions of routine operations. The newer methods of using local anaesthetics are mentioned, but the description of such procedures as sacral anaesthesia is not sufficiently exact for practical application; the same applies to the accounts of brachial plexus and splanchnic anaesthesia. Colonic ether anaesthesia appears to be used extensively in the author's practice. The objections from the surgeon's point of view to the high temperatures at which theatres are kept are emphasised, but one would like to see the necessity for conserving the patient's heat equally stressed. An account of the technique of blood transfusion is included. There is a curious omission of intratracheal anaesthesia as an aid to operations on the neck and mouth. The author still recommends laryngotomy in these cases. The script is worthy of illustrations of a higher order. Some of them are quite devoid of artistic merit, and, indeed, a few of them, as that on p. 117, are crude.

Altogether, this is a useful little volume and it will continue to be valued by students preparing for examinations.

Practical Surgery Illustrated. By VICTOR PAUCHET. Translated by F. R. B. ATKINSON, M.D., C.M. Edin. With an introduction by Sir CHARLES GORDON-WATSON, C.M.G., F.R.C.S., Surgeon and Joint Lecturer in Surgery, St. Bartholomew's Hospital. London: Ernest Benn, Ltd. 1925. Vol. III. Pp. 248. 18s. 6d. Vol. IV. Pp. 255. 15s.

THESE volumes follow the general plan of Parts I. and II. which have already been reviewed in our columns. It would have been more satisfactory if the sections dealing with one particular disease had been collected together. For instance, femoral hernia was treated in one of the earlier volumes and the operation above Poupart's ligament alone described, whereas in Vol. IV. we get a full account of the inguinal operation. Again, the chapters on gastric surgery are scattered through the four volumes. In Vol. III. there is a very good account of radicotomy, by J. A. Sicard and M. Robineau. The treatment of fractures by open operation is considered by Dujarier. This section does not come up to the standard of the rest of the work, as the author only treats of the matter in general and gives no details. The rest of the volume is written by Pauchet. He deals with cancer of the tongue, goitres, gastric and duodenal ulcers, tumours of the large intestine, and adenoma of the prostate. In cancer of the tongue he describes only one operation—the intra-buccal method. He recommends, however, that the

kind of operation performed should depend upon the situation of the growth. He believes that in the future radium will be used much more extensively than at present, but that now preference ought still to be given to surgical treatment without delay. The chapter on goitre is well illustrated. On carcinoma of the colon the author is at his best. The section on suprapubic prostatectomy is not of the same excellence. The fourth volume is a very good series of pictures illustrating operations upon the subjects treated therein. There is described an approach to the shoulder-joint through the axilla with which surgeons in this country may not be familiar. Good accounts are given of gall-bladder surgery and colostomy. In carcinoma of the breast the author removes the breast first and the axillary contents last, contrary to the usual British practice. He advises against very large incisions for exploring the abdomen; we agree that it is better to make one in the epigastrium and a separate one in the lower abdomen if necessary. The fourth volume is ill translated. The translator uses peculiar methods of construction and unusual words, and there are mistakes all through. For example, the following sentence appears on p. 178: "In amoebic dysentery, the mucosa presents a lunar appearance, with ulcerations in the form of a crater, a kind of substance with edges cut perpendicularly and often absent at the base, that two craters may be united by sliding a thread over the two bases of the ulceration." It is a pity that the work of a great surgeon should be thus mutilated.

SYMBOLISM OF THE THREE DEGREES.

By OLIVER DAY STREET. London: George Allen and Unwin. 1924. Pp. 195. 8s. 6d.

THIS is a work primarily written for Freemasons, but it is also of much interest to those who are not members of the Craft, for symbolism enters into daily life, and itself preserves ideas and customs which go back to the dawn of history. The Three Degrees are those of the Entered Apprentice, the Fellow Craft, and the Master Mason. Mr. Street gives a clear account of the meaning of the symbolism underlying these degrees. Masonic symbolism has incorporated and adapted much symbolism originally used with a somewhat different meaning; or, rather, the symbols of Masonry are like the different interpretations of the Scriptures—the literal, the allegorical, the tropological, and the anagogical. For instance, the square and the circle are two very ancient symbols which originally meant the world and the heavens. The ideal building and many early buildings were representations of the visible world and therefore planned square with a hemispherical roof. Owing to structural difficulties this ideal was not realised until the building of Santa Sophia, the first building in which a dome was correctly superimposed upon a square by the invention of pendentives. In Masonry the square represents the lodge, which is again symbolical of the world, and its covering is a "clouded canopy" (pp. 26 and 59). But in another sense the square represents morality or uprightness. Circumambulation again was originally a representation of the sun's apparent daily course. To go the opposite way—i.e., "widdershins"—meant death or something evil. So ecclesiastical processions always go from the east by way of the south aisle, except on penitential occasions, when they go by way of the north aisle, and even he who is least acquainted with symbolism knows that the bottle must be passed with the sun. Finally, we may recall the historic triangular duel between Mr. Biggs, Mr. Easthupp, and Mr. Midshipman Easy, when the gunner, who was consulted on points of procedure, replied with unerring intuition that in his opinion "they should fire with the sun." The science of numbers upon which Mr. Street discourses learnedly has always been of great importance in mystical lore. To give one example, the number of fishes taken in the miraculous draft mentioned in

St. John's Gospel, chap. xxi., was 153. These fishes are explained as the whole congregation of the elect, for ten stands for the Law and seven for the works of the Spirit; $10 + 7 = 17$, i.e., the fulfilment of the Law by the Spirit. Sum the progression $1 + 2 + 3 + 4 \dots + 16 + 17$, and the total is 153. So in Masonry we find the steps of the Winding Stair in sets of 3, 5, 7, all odd numbers adding up to 15, another odd number going back to the 15 steps of Solomon's Temple and the 15 Songs of Degrees.

To the many medical men who are Masons we cordially recommend this book; others who are not Masons will profit by reading it also.

EVOLUTION.

Living Organisms. An Account of their Origin and Evolution. By E. S. GOODRICH. London: Oxford University Press. 1924. Pp. 200. 6s.

AN admirable, and not the commonest, portrait of Darwin forms an appropriate frontispiece to a volume in which the Linacre professor shows how the great truths of Victorian comparative anatomy and evolutionary theory are illuminated, expanded, and confirmed, but never weakened or invalidated, by the newer knowledge. The chapters deal with the nature of life, reproduction and death, Darwinism and heredity, variation and the factors of inheritance, natural selection, isolation and sexual selection, phylogeny, the geological record, and psychological evolution. The treatment is close and in parts careful reading is necessary, but it is really a pleasure to come across an introductory book for adults which makes no pretence that difficult things are easy to understand and does not try to apply a Montessori method. Whether the "general reader" of the preface will be able to follow it all without more technical equipment than he generally has is rather doubtful. The book seems more suitable for students who have done an elementary course of zoology and botany, and we know of no better book to make them think; it will be excellent, too, for those whose formal instruction dates from last century, for medical men, for instance, who are in fact deeply concerned with the modern progress of biology and to whom it is too often represented in miraculous snippets, or as utterly subversive of what they grew up with. It would also, perhaps, be a useful discipline for some of the modern followers of genetics and such like who are apt to think that their new terminology has wiped out the older knowledge. The book is, in short, a sound scholarly attempt to get people to think accurately about evolution and heredity; it should meet with considerable success.

TUBERCULOSIS AND POSTURE.

Evolution de la tuberculose pulmonaire chronique dans ses rapports avec la circulation générale et locale. La cure décline. By Dr. PIERRE COLOMBAN. Preface by Dr. DUMAREST. Paris: Masson et Cie. 1924. Pp. 228. Fr.12.

THIS monograph is a plea for the postural treatment of pulmonary tuberculosis. Since 1919 the author has been systematically treating his patients by devices intended to promote congestion of the apices of the lungs, or at least to render them less anæmic. The couches and beds on which his patients lie are tilted at angles calculated, it would seem, to flush the head and neck as well as the apices of the lungs with blood. Most of the patients found suitable for this treatment were women, the author having discovered that they adapt themselves more readily than men to postures which, however salubrious, are apt soon to become most uncomfortable. It is doubtful if the author has brought forward a single new argument in favour of a system of treatment which was the vogue more than a decade ago in certain institutions. His book is, however, useful as a fairly comprehensive summary of the many arguments

adduced from time to time in favour of the view that man, in changing from the horizontal to the upright posture in the course of his evolution, has paid for this change with anæmic apices to his lungs. The inevitable corollary to this view, according to the author, is that man must, at any rate temporarily, return to the posture of his remote ancestors. It is difficult to picture the "missing link" tacitly submitting to some of the postures shown in the illustrations with which the text of this book is enlivened.

Reports and Analytical Records.

OLD'S ADVOCAT.

(WED. G. OLD AND CO., PURMEREND, HOLLAND. AGENTS FOR THE UNITED KINGDOM: G. IDLE, CHAPMAN AND CO., LTD., 65, LOWER THAMES-STREET, E.C.3.)

THIS is a thick yellow liqueur tonic having a pleasant flavour suggestive of a sweetened mixture of egg and brandy. When analysed the following results were obtained:—

Alcohol	14.4 per cent. by weight (equivalent to 31.1 of proof spirit).
Total solids	37.3 per cent.
Consisting of—	
Sugar	22.1 "
Gums, &c. . . .	2.0 "
Protein	3.3 "
Ether soluble matter (fats, &c.)	2.73 "
Ash	0.16 "

These figures are consistent with a composition of:—

Egg in natural condition	25 per cent.
The equivalent of brandy of 30 U.P. . . .	50 "
Sugar	23 "
Gum, &c. . . .	2 "

Salicylates, benzoates, borates and sulphites were tested for with negative results.

Advocaat, as will be seen from this analysis, is a nutritious preparation of brandy, sugar, and egg in the form of a stable and homogeneous emulsion. The trouble saved by beating eggs and mixing with sugar and brandy, and the absence of preservatives, render Advocaat a useful and palatable food tonic which is available at all times.

MORUETTE COD-LIVER OIL TABLETS.

(MESSRS. ARTHUR H. COX AND CO., MANUFACTURING CHEMISTS, BRIGHTON.)

WE have received a sample of Moruette Cod-liver Oil Extract in tablet form in the convenient little cases in which the preparation is distributed. The value of cod-liver oil as a medicine needs no insistence; if the claims made for it have been too wide in some directions and too high in others, there is no doubt that cod-liver oil is a most valuable substance in the hands of the physician, who has, however, found that the nauseous properties sometimes interfere with the efficacy. Consequently much ingenuity has been employed by chemists to provide palatable forms for the administration of the drug, and these tablets are made from the extractive only. They possess the vitamins and cholesterol content, the susceptibility of these bodies to heat having been provided for in the preparation of the extractive. The extractive is said to enjoy considerable popularity on the continent, but in England it is as yet not often prescribed.

OSYL ANTISEPTIC SHAVING-CREAM.

(LYSOL LIMITED, LONDON, S.W. 20.)

THIS firm has sent us a preparation of shaving-cream put up in a well-made screw-topped collapsible tube. It need hardly be said that a shaving preparation based on lysol, with its qualities as an antiseptic and solvent of grease, has two great things to recommend it; a third recommendation may here be mentioned—application of hot or cold water produces a copious lather almost immediately.

THE LANCET.

LONDON: SATURDAY, MARCH 7, 1925.

THE LONDON INSURANCE COMMITTEE: A SAD IMPASSE.

It must be known to many of our readers that the Medical Service Subcommittee of the London Insurance Committee has withdrawn from the deliberations of the Committee. This means that the important and delicate duty of dealing with the complaints which arise among a million and a half insured persons in the County of London remains in abeyance, and we need hardly say that a position like this, lasting for three months, is acting as a terrible clog upon work. There are, for example, 15 complaints ready now for hearing, while twice that number of cases are in an early stage of preparation, and no meeting at which the merits of the cases may be adjudicated upon can be held unless there are present at least one medical man and one representative of the insured persons. Thus the absence from the meetings of the medical members, who no doubt are abstaining at the instance of, or with the approval of, those who appointed them to their duties, holds up the work of the Subcommittee till further notice.

We have called this position a sad impasse because it has arisen in circumstances from which at first sight no escape seems to be provided; but we refuse to believe that a working solution of the difficulties will not be forthcoming without delay, when the grave responsibility lying on all concerned is recognised, and the danger of the existing inaction is realised. Without going into minutiae, or even details, the position has arisen in the following manner. The medical members of the Subcommittee desired to work under a new chairman, believing that the present occupant of the chair does not, from their point of view, exercise full impartiality. The laymen of the Subcommittee, resenting what they consider an unjust imputation, have refused to be nominated in succession to their present chairman, who therefore remains in his old position, which he has occupied for a considerable period. The medical members of the Subcommittee in their turn resent the appearance of having acted without due motive, and are especially sore at the imputation that the chairman has become personally distasteful to them because he is too alert to prevent them from protecting medical practitioners during the hearing of complaints. So the chairman will not resign, for that would look like a confession of failure, and the medical members will not sit under him, while without their presence complaints cannot be heard. To us it seems clear that the situation ought not to be beyond the aids of statesmanship and courtesy on each side, while both these qualities should be exercised at once on behalf of an enormous insured population. The Ministry of Health must otherwise be called in to adjust matters, while a far pleasanter milieu for the future would be created if the various persons concerned could come to an agreement on their own initiative. The first step to such an agreement must be the withdrawal of recriminations, and where there are categorical instances in which the chairman has appeared to show bias they should be frankly stated and equally frank explanations should be

forthcoming. If this procedure were adopted surely one of two things would occur—either the neutral section of the Subcommittee, in whom the election is vested, would admit the justice of the view of the medical men, and allow one of themselves to be put forward as chairman, or the medical members, listening to the considered explanations of the chairman as to his conduct in particular matters, would consent again to attend the meetings. And if unfortunately none of these things occurred the Ministry of Health could then be asked to intervene. We know that the Ministry has official cognisance of the whole matter, and already some official steps may have been taken.

BISMUTH THERAPY IN SYPHILIS.

The value and limitations of bismuth therapy in syphilis is the subject of a review by Dr. E. T. BURKE in the first number of a new quarterly journal entitled the *British Journal of Venereal Diseases*.¹ Numerous insoluble preparations of bismuth in aqueous or in oily suspension, as well as soluble preparations, have been placed on the market by chemical manufacturers in recent years and their specific value in syphilis has been much discussed. Dr. BURKE summarises in simple words the conclusions which LEVADITI has arrived at after a great deal of work on the pharmacology of the chemical group which includes arsenic, antimony, vanadium, and bismuth. These substances are alike in the fact that, while the parasitocidal power of their salts in simple solution in vitro is zero, when combined with certain tissue extracts they exert a destructive action upon protozoal organisms. Bismuth, whether in metallic form or in the form of salts, is an inert substance which can be changed by some constituent of the tissues, known for convenience as bismogene, into a new compound of unknown constitution called bismoxyl, and in this form is of high therapeutic value. From experimental evidence it would appear that bismuth compounds must be reduced to elemental bismuth before bismogene can act and give rise to bismoxyl; but Dr. BURKE prophesies that in the near future means will be found to administer bismoxyl directly to the patient instead of, as at present, depending on his own tissues for an activating substance. For the moment, however, the choice lies between the soluble and the insoluble forms of bismuth at present available for therapeutic purposes. Dr. BURKE holds that the soluble salts possess certain practical disadvantages; on account of their rapid absorption they are liable to cause toxic effects; and, owing to their equally rapid elimination, their therapeutic value is diminished. Moreover, after their use stomatitis, nephritis, and painful nodosities at the site of injection are apt to occur. Injection of insoluble preparations suspended in oil gives little pain, but the rate of absorption is slow. Metallic bismuth in very fine subdivision is painless when injected, the rate of absorption is satisfactory, and nodosities are as rare as are any untoward effects of a toxic character. Further, since reduced bismuth is necessary for the production of bismoxyl, this is clearly the most scientific form in which to administer the element. The injection of metallic bismuth, rather than one of its compounds, is a stage nearer to the giving of already prepared bismoxyl, and in Dr. BURKE's experience the results are better and are more quickly obtained with metallic bismuth than with any other preparation. Exactly

¹ The *British Journal of Venereal Diseases*. Edited by L. W. Harrison and E. R. T. Clarkson, with 13 sectional editors. London: Constable. Published by the Council of the Medical Society for the Study of Venereal Diseases.

similar conclusions were reached by LEVADITI, who now uses neo-trépol, a suspension of metallic bismuth in isotonic saline.

Dr. BURKE's treatment of a patient caught at the primary stage extends over 24 weeks—eight weeks during which stabilarisan is injected once weekly, followed by four weeks of bismuth therapy in the form of injections of metallic bismuth (bismostab) three times a week. This 12 weeks' course is then repeated without any interval. Reliance is placed chiefly on arsenic for the rapid healing of superficial lesions. Alternate rather than concurrent courses are the rule, since the spirochaetes must not be allowed to acquire such familiarity with either drug as may breed contempt for its lethal powers. The absence of mercury from this programme will be noticed. Dr. BURKE states boldly his opinion that mercury has become obsolete in the treatment of syphilis. He assesses the potency of the three specifics in the order, arsenic, bismuth, mercury, as 10 : 8 : 3. It is clear that in Wassermann-fast cases, or in those which exhibit intolerance to arsenobenzol, bismuth is the drug of election. Dr. BURKE enumerates and classifies the various preparations of bismuth on the market, gives reasons for his preferences, and includes a detailed account of a technique designed to spare the patient the gluteal pain or general discomfort which may follow intramuscular injection in inexperienced hands. This part of Dr. BURKE's survey, which is based on an extensive personal experience of bismuth therapy, will be found valuable. In an article ambitiously labelled "a critical review," however, a more detailed reference to the literature in the appended bibliography would have been welcome. No mention is made of the excellent monograph by LEVADITI and NICOLAU (*Annales de l'Institut Pasteur*, 1924, xxxviii., 179) wherein all the original experiments on bismoxyl are described; those readers who are interested in this fascinating subject from the theoretical standpoint will do well to consult this monograph, as also the summary of the growth of bismuth therapy contributed to our columns by LEVADITI himself two years ago.²

To the same journal, which is rich in articles of direct clinical as well as scientific interest, Dr. SVEND LOMHOLT, from the Finsen Light Institute, Copenhagen, contributes notes on the pharmacology of bismuth with a similar reference. He has less scorn for mercury than is exhibited by Dr. BURKE, admitting that possibly the therapeutic effect of bismuth may be slightly less than that of strong mercurial treatment, but he contends that bismuth is better tolerated and is more convenient to use. In his view the principal objection to its use is that it may give rise to the formation of a typical blue line at the margin of the gums, and, though this causes no discomfort, patients may object to the risk of being thus branded. Prevention of this discolouration is thus of paramount importance. When preparations are used which are absorbed slowly, the bismuth line may develop and increase in strength for some time after the administration of the drug has been stopped. For this and other more important reasons, such as the prevention of toxæmia, Dr. LOMHOLT holds, in contradistinction to Dr. BURKE, that the preparation chosen should be quickly and regularly absorbed and quickly eliminated, while the selection should also be influenced by the degree of pain and discomfort caused after injection. Since the rate and regularity of the elimination of any preparation varies directly with its rate and regularity of absorption, Dr. LOMHOLT conceived the idea of examining the excretions for bismuth in

a number of patients under treatment. He examined various preparations, first in oily and then in watery suspension, and came to the conclusion that watery suspensions or solutions must be preferred for practical use, and that of various compounds examined bismuth hydroxide suspended in water, to which a small amount of glycerine is added for the sake of stability, was the most suitable drug. He adds details of the simple laboratory method of preparing bismuth hydroxide which has given every satisfaction in his hands. Bismuth in metallic form was not among the preparations investigated by LOMHOLT.

The conclusions of different observers of the action of a drug comparatively new in the therapeutics of syphilis are likely enough to vary, inasmuch as each sees this complex medico-sociological problem from a different view-point. The related questions of convenience of administration, of pain after injection, of concealment of the nature of the disease, of the length of the period of treatment are matters which depend on the class and circumstances of the patient as well as on the bias of the practitioner; these and many other factors may have a bearing on the preparation of bismuth or any other drug chosen as a routine. In this connexion it may be emphasised that arsenic still holds the premier place in the treatment of syphilis, and it would appear possible that the most important function of bismuth is to kill off those spirochaetes which have become immune to arsenic. In a sympathetic introduction to this first issue of a new venture in medical journalism Sir HUMPHRY ROLLESTON notes that critical reviews will be a feature of each quarterly number. We suggest that a review of new developments in arsenic therapy, in the light of FOURNIER'S and FOURNEAUX'S discovery of acetyl oxyamino phenyl arsenic acid would be appreciated by many practitioners. This substance, known as 190 or stovarsol, when given by the mouth within five hours of exposure to infection is said to protect against syphilis, and LEVADITI, in an address before a Conference at the Institut Pasteur in April, 1923, said that it possessed "une valeur démonstrative incontestable." Little is heard of this body in England, yet clinical trials abroad would seem to show that it marks a more profound advance in the therapeutics of syphilis than any preparation hitherto produced.

MENTAL DEFECTIVES IN PRISONS.

It is to be hoped that Parliament will some time take steps to amend the Mental Deficiency Act in the manner proposed in the Report of the Prisons Commissioners for the year 1923-24 (1925, Cmd. 2307). The Act of 1913, it will be remembered, begins by separately defining four classes of defectives—namely, idiots, imbeciles, feeble-minded persons, and moral imbeciles. In the case of the first three of these classes the definition requires proof that the mental deficiency has existed "from birth or from an early age"; in the fourth class the permanent mental defect of the moral imbecile must have been displayed "from an early age." The inclusion in the Act of the words which we have quoted has the unfortunate effect that many defectives cannot be certified and admitted into an institution even where the defect is plain. As the medical officer of Holloway Prison points out, for example, it is often impossible to ascertain the early history of the elderly debilitated women who are received at his prison, many of whom have a great number of previous convictions. These unhappy men and women too often find their

² THE LANCET, 1923, i., 639.

way into the population of our prisons to the detriment both of themselves and of the community. The Commissioners state clearly and unanswerably that prison life is the wrong environment. Persons whose mentality is not normal yet who are technically not certifiable are not amenable to full prison discipline and can derive no benefit from prison training; at the same time their presence is an obstacle to the training of the normal prisoner. As a temporary arrangement the Commissioners are assembling persons of this type (where the sentences are of sufficient length to justify transfer) at certain prisons where they will be located together and receive the kind of treatment appropriate to their condition. It is explained, however, that this is merely a palliative measure. Prison resources are not available to deal with the problem properly. Parliament must meet the difficulty. The admirable extracts of the views of medical officers of particular prisons (appended as usual to the Commissioner's annual report) emphasise the fact that the Mental Deficiency Act must be amended. The prison doctors at Holloway, Manchester, Norwich, and Preston speak specifically of the results of this difficulty of certification. The medical officers' commentaries are always interesting and often challenging. We notice in connexion with "moral imbeciles" some robust remarks from the doctor at Wormwood Scrubs, who criticises the belief in the irresponsibility of such offenders—a belief which he attributes to the philosophical doctrine of determinism. The Wandsworth Prison doctor observes that the solution of the problem of what to do with the "criminally mentally unstable and people with a criminal kink" cannot be found "until there is a fundamental change in the present incomprehensible attitude of sympathy for the prisoners and forgetfulness of those who have suffered by their being at large."

From Manchester comes a proper condemnation of the practice of magistrates who sentence a prisoner to a term of imprisonment and then ask that his mental condition be kept under the observation of the medical officer of the prison. It is obvious that, in cases where an accused person's mental state is in question, there should be a remand for the necessary observation and report before conviction and not after. It is satisfactory that the Commissioners can say that there has been less difficulty than in previous periods in finding accommodation in institutions for certified defectives; the certified cases thus have a shorter period to remain in prison before removal. Another commendable feature of the report on a matter of general public health is the concurrence of medical opinion, especially from the prisons of Birmingham, Holloway, Hull, and Leeds, as to the noticeable diminution in venereal disease. There is, as the medical officer at Birmingham truly observes, a vast amount of valuable clinical material in our prisons which is at present wasted for lack of research workers.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The annual general meeting of this association will be held at 1, Wimpole-street, London, W., on Wednesday, March 18th, at 5.15 P.M. At 6 P.M. on the same day a discussion on Post-graduate Teaching in London will be held, when Sir Arbuthnot Lane, President of the Fellowship, will preside. All members of the medical profession are asked to attend and to give their criticisms of the existing Fellowship arrangements and suggestions for their improvement. On Wednesday, March 11th, Mr. Oswald Addison will lecture for the Fellowship on Cleft Palate at 1, Wimpole-street, at 5.30 P.M. Copies of the syllabus of the special courses, together with the Fellowship Bulletin, will be sent on application to the Secretary to the Fellowship, at 1, Wimpole-street.

Annotations.

"No quid nimis."

THE BOARD OF CONTROL.

SOLICITUDE for the insane, when it has not found expression in destructive abuse of an ill-defined "system" of lunacy administration, has in recent times taken the form of a critical observation of the activities, actual and potential, of the Board of Control. The clamorous and contradictory demands that reach us from various quarters for the extension, the curtailment, or the abolition of the powers of the Board suggest that many medical men are unfamiliar with the respective duties and limitations of the various authorities charged with the control of the life and property of persons deemed incapable of taking care of themselves. The Board of Control is generally known and accepted as the central authority for mental disorders, and is thus a convenient target for criticism. The two other Government departments concerned in lunacy matters in England are the office of the Master in Lunacy and that of the Lord Chancellor's Visitors. A third department—the Home Office—is involved in the case of the insane criminal. In order to appreciate this complex arrangement it must be remembered that, apart from the insane criminal, development has taken place along two distinct lines. Authority was at first concerned only with the property of the insane. The care and treatment of patients is a much later development in the historical sense. In feudal times the land held by persons unable to perform their duties by reason of mental defect or disorder no doubt reverted to the feudal lord who found a more suitable tenant. As far back as the reign of Edward I. we find the Crown claiming an interest in the property of idiots and persons of unsound mind. The Royal prerogative became established, and exists to-day in the clearly-defined powers of the Lord Chancellor, and the offices of the Master in Lunacy and the Lord Chancellor's Visitors. The Master now administers the estates of persons of unsound mind, where proper application is made. The Visitors have special duties in visiting, and reporting on the care and comfort of those whose affairs are in the hands of the Master, and the diminishing number of patients found insane by inquisition. These two offices are distinct one from the other, though a united Board meeting is held monthly. Moreover, both are distinct from the Board of Control, a fact which produces confusion in visitation and reports concerning patients. For example, one of the medical Visitors of the Lord Chancellor may arrive to visit a patient on the same day as a Commissioner of the Board of Control; and the Master may ask the medical officer of an institution to report on the mental and physical health of a patient concerning whom a full report has just been transmitted to the Board of Control. Were it possible to amalgamate these offices, so that information concerning patients would be common to all, visitation would be simplified and unnecessary reports abolished. Such amalgamation has been attempted on three occasions, but without result, although the step has received the support of at least one of the Masters in Lunacy, and no doubt would be welcomed by the Board of Control.

The authority for the care and treatment of patients is the Board of Control. Its name is not perhaps well chosen, being reminiscent of liquor control or a railway commission; the term Board of Mental Health has been put forward as a more suitable description. The Board had its origin in 1774, when the Royal College of Physicians of London was appointed to exercise statutory functions in connexion with lunacy. Thus the nucleus of a central authority was formed, and later legislation finally established the Commissioners in Lunacy in 1845 as an autonomous body. The first chairman

was the seventh Earl of Shaftesbury who did so much to promote the proper care of persons suffering from mental illness. This Commission existed until 1913, when the Board of Control was constituted by the Mental Deficiency Act. The Board is a corporate body with a common seal, and consists of not more than 15 Commissioners, of whom not more than 12 are paid. At least four are medical practitioners, and four are lawyers; one of the paid and one of the unpaid Commissioners must be a woman. The legal Commissioners are appointed by the Lord Chancellor, and the others by the Minister of Health, who appoints the chairman. There are also four inspectors, one being a woman, appointed by the Board and approved by the Minister of Health, all being paid, though at a lower rate than the Commissioners. This Board, in addition to its duties concerning mental disorders, has the supervision of mental defectives of all classes, whether housed in institutions or elsewhere. An affiliation with the Ministry of Health took place in 1920 by an Order in Council, whereby the powers and duties of the Home Secretary under the Lunacy and Mental Deficiency Acts were transferred to the Minister of Health who represents the Board in Parliament. The Board publishes annual reports of its work, volumes which contain valuable statistics, and much detailed information of the visitations carried out during the year. These reports might be more widely read with advantage, especially by those who seek to attribute deficiencies in accommodation, staffing, or diet in public mental hospitals to neglect on the part of the Board. Year after year in some counties and boroughs the attention of the local authority is drawn to manifest defects in the hospitals under their care, and recommendations are made which the central authority is not able to enforce. The Board is an advisory and not an executive body in respect to public mental hospitals, and of the many proposals that have been made with the object of strengthening the central authority none is more likely to lead to good results than an extension of its powers in this direction. Until the central authority is in a position to insist on improvements to buildings, and on reforms in other important departments, progress will be slow, and any suggestions from medical superintendents involving a large increase in the expenditure per patient will be ignored.

Certain other criticisms which have been made against the existing organisation appear to be of less fundamental importance. The justification for such a large legal representation on the Board has been questioned. It is true that the care and treatment of the mentally afflicted has legal aspects, but it is mainly the duty of the medical profession to carry out both care and treatment in practice. There is a growing feeling that visitation should not be made by legal Commissioners alone, but that they should be accompanied by one of the medical members of the Board. Some patients doubtless like to see a legal Commissioner, with whom to discuss the question of detention and so forth, but at a time when the treatment of mental disorders is demanding keen medical attention a barrister or solicitor seems out of place as the inspecting visitor of an institution. In years gone by there was a tendency on the part of the Commissioners to remain aloof from the medical work of the day. This cannot be said of the present Board, but it is of the first importance that the medical members should be preponderant thereon, and that they should continue to be of high professional standing and experience. It has been said, also, that the Board has been inclined to insist on certification unnecessarily in some institutional cases, when voluntary treatment might have been carried out with success. Here there has been latterly a definite change in the policy of the Board, and certain cases that can be managed safely on a voluntary footing are now allowed to remain whether certifiable or not. It is to be hoped that the voluntary principle in treatment may be extended, and that rate-aided patients may shortly obtain the privilege of seeking

voluntary treatment, opportunity for which is now confined to the private class. The Board has been blamed in some quarters for neglecting to initiate more prosecutions for breaches of the Lunacy Acts, especially where persons of unsound mind have been detained for payment in places other than recognised institutions. This is a matter which bristles with difficulties. Reliable evidence is often not forthcoming, medical men may differ, and public opinion is often hostile, a sentiment that is readily reflected in the verdict of a jury. The policy of the Board in this matter must be allowed to be largely dependent upon the nature and circumstances of each individual case. There is a general dissatisfaction with that part of Section 315 of the Lunacy Act, 1890, which concerns the misdemeanour of receiving an "alleged lunatic" for payment without certificates in an unlicensed house. Clearly such a person should not be allowed to be detained. But, if harmless to himself and others, why should not such a patient be allowed to remain voluntarily if he wishes? For early cases especially it would be useful to avoid certification, always provided that adequate skill and treatment were available, and notification was made to the Board of Control.

It is well known that informed opinion is divided as to the future of the central authority for mental disorders. One group of critics would endow the body with more authority, another would limit its activities to mental institutions and single certified patients only, and transfer the supervision of the care and treatment of incipient and borderline cases to another authority. The object of this school appears to be to divorce the early case from the machinery that is unhappily labelled "Lunacy." Something has been said of the confusion that already exists as a result of departmental independence. Is further division desirable? Attempts at establishing a separate authority for incipient and borderline mental cases might well prove a retrograde step. Should the work of the Board of Control become greatly increased by the measures foreshadowed in recent Bills framed to amend the Lunacy Law, it might well be that more officials would be required, and the question of decentralisation of some of the duties of the Board might then have to be considered; but any radical alteration in its status or limitation of its responsibilities to the care of advanced cases only would, we believe, be deprecated by all who know the difficulties of dividing established from borderline cases. Mental disorder, incipient or developed, is one large problem. Certifiability is strictly a legal conception, arbitrary, and not altogether satisfactory; indeed, a patient may be certifiable one day and not certifiable the next. The lesson of history teaches that mental disorder has characteristics which require care and treatment to be carried out with special precautions, demanding the guidance of a well-organised and well-informed central authority, having full powers of inspection and visitation to all places where mental disorder is treated, whatever its degree. The authority responsible must be a progressive medical body, sufficiently assisted by legal advisers, and adequately remunerated; and it should be able to care both for the patient and for his property.

INTERNAL FIXATION OF FRACTURES.

ALTHOUGH a good many years have passed since Sir Arbuthnot Lane introduced his method of treating fractures by fixation with metal plates and screws, surgical opinion is still divided as to the general applicability of it, and there is no accepted consensus of opinion as to the class of cases in which the operation should be performed. Much has been said and written as to the alleged bad effect of the metal in causing absorption of bone, but it is not yet proved that this is a necessary or even a very frequent result of plating. In these circumstances an endeavour to sum up experience of the results of various methods of internal fixation in fractures is very welcome. Dr. E. L. Eliason and

Dr. Drury Hinton have attempted this in a paper published in Vol. IV. of the Thirty-fourth Series of International Clinics,¹ and although the experience dealt with by them is practically confined to the United States, the lessons to be learnt are of universal application. The annual casualty list among civilians in the United States would not disgrace a war of moderate or Victorian proportions, and although deplorable it has the grim advantage of affording to American surgeons unrivalled opportunities of studying injuries in peace-time. The authors justly lay stress on the importance of what they call muscle equilibrium as well as extension after plating. By this is meant the placing of the affected limb in such a position that the tonic contraction of the muscles does not tend to distort the fractured bone. For instance, in the case of a fracture of the femur in its upper half, which is being treated in the fully extended position, the action of the ilio-psoas and of some other muscles tends to produce angulation at the site of fracture and displacement of the plate. This circumstance accounts for some bad results after plating, which can be avoided by using the semi-flexed position combined with extension in the line of the thigh. This paper is illustrated with a number of radiographs, many of which show Lane plates embedded in bone 10 to 14 years after their application. The authors sum up their experience in 13 conclusions. They recommend internal fixation, when repeated attempts at correction have failed, when reduction cannot be maintained, and in certain compound fractures. They prefer plates to bone-grafts except for cases of non-union, but would totally exclude their use in fractures of the forearm. There is no doubt that Lane's method, like many other procedures, has been discredited because enough discrimination in selection of cases has not been used, and less often perhaps because of faulty technique and want of experience and skill. Good judgment and training and a proper appreciation of simple mechanical principles should be possessed by all operating surgeons, but above all, by those who would obtain the best functional results in the cure of broken bones.

TUBERCULOSIS OF THE MAMMARY GLAND.

ACCORDING to Dr. James A. Cahill, jun.,² surgeon to the Providence Hospital, Washington, who records an illustrative case, tuberculosis of the mammary gland, which was first described by Sir Astley Cooper in 1829 under the name of "scrofulous swelling of the breast," is an extreme rarity. Lancereaux, in 1860, was the first to make a diagnosis from histological examination. DuBarr, in 1881, distinguished two types, the nodular or discrete and the confluent. Deaver, in 1914, collected 74 cases from the literature between 1904 and 1914, five of which had occurred in his own practice. According to Dr. Cahill, tuberculosis of the breast, which is almost invariably limited to one side, may be described under three distinct types—viz., the disseminating, the confluent, and the sclerosing. Infection of the breast, like that of other glands, takes place by the lymph, blood, or direct extension, as well as through the skin itself by means of a cracked nipple. In the nodular or discrete form a small lump is found in the breast, usually in the upper and outer quadrant. In the early stage the gland is movable, the overlying skin is glossy, and later becomes red and inflamed. The nipple may become retracted early or late. Enlargement of the axillary glands is present in about half the cases in the early stage. The growth is usually slow and is not painful until necrosis has occurred and the whole breast has broken down. In the later stage the axillary glands become involved in about 70–80 per cent. and necrosis occurs. In the disseminating type the nodules remain distinct

and there are numerous large areas of necrosis. The sclerosing type is characterised by a diffuse hardening which overlies deep abscesses or, less frequently, by the whole lesion being entirely fibrous. Tuberculosis of the mammary gland is essentially a disease of the female sex, only 11 cases having been reported in males; 70 per cent. of Deaver's cases occurred between the ages of 20 and 50. Trauma is an important factor. The condition may be primary, involving the mammary gland itself, or secondary to some focus elsewhere in the body. The following conditions must be excluded from the diagnosis: Carcinoma, fibroadenoma, interstitial mastitis, actinomycosis, gumma, chronic and pyogenic infections. The prognosis is good in the primary type if complete amputation of the breast is carried out. In the second type the outlook depends on the primary factor or the pulmonary condition plus removal of the breast. Treatment consists in complete removal of the breast, dissection of the axillary glands, and removal of the pectoral muscles if the glands are involved. Dr. Cahill's case is remarkable as having occurred in a girl aged 13, the symptoms appearing within a month of a blow on the left breast. Complete recovery followed removal of the organ.

SANOCRYSYN: AMERICAN CRITICISM.

IT is interesting to note that the comments in the *Journal of the American Medical Association* (Jan. 24th and Feb. 14th) on the evidence hitherto advanced in favour of sanocrysin as a chemo-therapeutical remedy for tuberculosis coincide closely with those put forward in a recent issue of THE LANCET.¹ It is, moreover, suggested that in connexion with sanocrysin it is only the name that is new. The toxic properties of the salt are emphasised, and it is pointed out that all the therapeutic effects were produced by a combination of the salt and serum. Attention is also called to the dangers of using only one control animal in each batch of experiments, since it is well known that the individual susceptibility of animals to tubercle cultures varies widely. Again, the virulence of the cultures used in the experiments with calves is called into question and the experiments with tuberculous monkeys are considered to be of little value, since the evidence upon which the diagnosis of infection was made was insufficient. The possibility that the post-mortem findings upon infected animals killed with sanocrysin were not due to tuberculin shock but to metallic poisoning is put forward with some force. The crucial therapeutic experiments are being repeated in the United States Public Health Service Laboratories before the remedy will be allowed upon the market in that country, and the wise advice given to the public is of general application—"to await patiently the knowledge that will come from carefully planned experiments now under way."

AUSCULTATION OF JOINTS.

IN *Wiener Klinische Wochenschrift* of Feb. 5th Dr. Edmund Maliwa, Baden, contributes an interesting article on the subject of auscultation of joints. The large group of the chronic arthritides is notoriously the stepchild of internal medicine, not only as concerns the teaching of students, but also with regard to the scientific interest of the research worker. Treatment is therefore ineffective and prognosis unsatisfactory. One of the most important parts in the physical examination of the joints in cases of chronic arthritis is palpation of the affected part. But palpation and examination by radiograms sometimes fail in joints in which the affection soon afterwards appears. Naturally the idea comes up whether there are not crepitations outside the limits of palpation which are only perceptible acoustically. The best analogy is found in a perisplenitis which is audible but cannot be felt. The crepitation may be too deep-seated or the fineness may be below per-

¹ International Clinics. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U.S.A., with collaboration. Vol. IV. Thirty-fourth Series, 1924. London: J. B. Lippincott Company, 1924. Pp. 308.

¹ THE LANCET, Jan. 31st, p. 239.

ceptibility and therefore below the stimulus-threshold of palpation. Auscultation must be properly carried out. It is implicitly recommended that a binaural stethoscope be used with a small sound disc—the latter must be placed firmly on the skin. In choosing the position of auscultation, in order to avoid artificial noises, it is important to select one which remains undisturbed while the movement is carried out. Further, the positions of auscultation should be as near as possible to the joint. Perception of crepitations at an early stage is extraordinarily helpful in confirming a diagnosis. In this connexion it is pointed out that the conditions for the transmission of sounds in general in the joints are very favourable. With practice it is possible to acquire a conception of the rougher and finer structure of the source producing the crepitation and also whether it is diffuse and concerns the whole joint, or is localised. Affections of the para-articular tissue, without affection of the joint in the narrower sense, are more easily defined diagnostically. The diagnostic advantages are so satisfactory, the judging of certain cases is made so much easier that it is rightly and urgently recommended that this method of diagnosis should be introduced in the normal course of the physical examination of joints. In the study of the literature pertaining to the subject published during the last 30 years, which includes about 600 papers, only one reference, by Garrod in the Royal Society of Medicine, January, 1911, is to be found. It is indeed curious that the auscultation of joints up till now has scarcely been used.

HEALTH ADMINISTRATION UNDER RURAL DISTRICT COUNCILS.

IN the past it was almost the invariable custom for one of the local practitioners, who might or might not be interested in administrative health problems, to be charged with the duties of a medical officer of health of a minor local authority, such as a rural district council. Theoretically this part-time system, which is still largely adopted, is well adapted, on the one hand, to bring practitioners into touch with questions of public health, and, on the other, to ensure that the medical officer of health has sympathetic understanding of the difficulties with which his colleagues in private practice have to contend. In practice, however, it is often found that those who are zealous practitioners care little for administrative work, and that the combination of two or more districts to appoint a whole-time medical officer of health proves to be the more satisfactory arrangement. Especially is this so when the medical officer is permitted to enlarge his experience by accepting part-time duties as tuberculosis officer or school medical officer under the county council. The remuneration which should be paid to such a medical officer has recently been under consideration by the British Medical Association in conjunction with the Society of Medical Officers of Health; the conclusion arrived at is that the combined remuneration for all work undertaken should be not less than the minimum commencing salary of a whole-time medical officer of health, as indicated by the population of the combined areas. An alternative way of securing public health administration of rural districts too small to justify the appointment of a full-time medical officer is to permit an assistant medical officer under a county council to become a district medical officer for a definite proportion of his time—say, a half-day per week. Such an assistant medical officer should, in the opinion of the two organisations who have been considering these questions, be paid at the rate of £80 per annum for each half-day per week spent in the service of the rural district, and his salary from the county council should be reduced by one-eleventh for the same period. For example, if he were being paid at the rate of £600 a year he would stand to gain £26 a year, as well as valuable experience by undertaking the duties of district medical officer of health for one half-day a

week. The opportunity of doing work of a more or of a less specialised nature than that which occupies him as a rule should make an appeal to an enthusiastic officer in the public health service. Both suggestions are likely to be appreciated by those who wish to be conversant with every branch of their speciality.

AN EPIDEMIC OF SPIROCHÆTAL JAUNDICE.

THE danger of infective jaundice becoming a disease of practical importance to medical officers of health in these islands is emphasised by an interesting article in our present issue. Prof. D. Murray Lyon and Dr. G. Buchanan describe a minor epidemic affecting two families in Edinburgh in the late summer of last year. In the first family four of nine persons were affected, and in the second three other children, playmates of the first family, suffered later from the same disease. In all cases the most prominent features of spirochætosis icterohæmorrhagica were observed—fever with malaise, headache, and joint pains being followed by jaundice with marked gastrointestinal disturbances, whilst a tendency to hæmorrhage, epistaxis, hæmaturia, hæmatemesis, and extravasations of blood under the skin was a common feature. The nature of the infection was confirmed by laboratory tests; blood from early cases, and centrifuged urine from later ones, was inoculated into animals, guinea-pigs, and mice, and in six cases lung hæmorrhages were produced. But the difficulty of obtaining full confirmation of the clinical diagnosis in these cases is shown by the fact that in only one of 44 laboratory animals inoculated were spirochætes demonstrable in the lung lesions after death. In spite of very careful search and examination of rats, mice, and domestic animals in the district where the epidemic occurred no spirochætal infection of this nature was discovered which might account for the human cases, and the origin was probably due to direct infection from a child visitor who had recently arrived from the Malay Peninsula and who had had an attack of febrile jaundice. In view of the frequency with which mild cases of spirochætosis icterohæmorrhagica have occurred without jaundice it is remarkable that this symptom was noted in every one of the present cases. The Edinburgh authorities are to be congratulated on the thorough way in which they have investigated a difficult problem. Since the war minor epidemics of spirochætal jaundice have been reported in France, in Sweden,¹ and in other European countries. There was an epidemic of obscure hæmorrhagic jaundice in New York in 1922,² and in 1924 Prof. Lovell Gulland and Dr. G. Buchanan reported³ an epidemic, proved to be spirochætal, amongst miners in East Lothian.

WE regret to record the death of Dr. J. J. Graham Brown, consulting physician to the Royal Infirmary, Edinburgh, on Tuesday, March 3rd, at the age of 71.

AT the election on Tuesday last for a representative of the Faculty of Medicine on the Senate of the University of London Sir Holburt Waring retained his seat with 67 votes, as against 57 given for Sir G. Lenthal Cheate.

THE King has appointed Dr. John Cowan to be one of the honorary physicians to His Majesty in Scotland in the room of the late Sir James Mackenzie. Dr. Cowan is professor of medicine in the Anderson College of Medicine, Glasgow.

THE next Social Evening of the Royal Society of Medicine will be held at 1, Wimpole-street, London, W., on Monday, March 16th, when the President, Sir StClair Thomson, will receive the guests at 8.30 P.M. Dr. H. Charles Cameron will give an address in the Robert Barnes Hall at 9.30 P.M. on "John Locke, the Philosopher (1690), on the Upbringing of Children."

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXII.—THE TREATMENT OF ANOREXIA IN CHILDREN.

THE treatment of a child who has lost inclination for food will always be one of the commonest problems which the practitioner is called upon to deal with, but it will not always be one of the easiest. One reason for this is that the trouble appears at the onset to be so trivial, so likely to right itself spontaneously, that the medical adviser usually does not see the child until a series of domestic remedies have been employed and have failed. At this stage of affairs the causal factors of the original anorexia may have been obscured by its results, rendering the exact nature of the trouble extremely difficult to determine.

Owing to the multiplicity of causes it is quite impossible to propound any line of treatment which will be applicable to every case of anorexia, and the administration of a "pick-me-up" without thorough investigation of the underlying cause is strongly to be deprecated. In every case a physical examination of the child should be carried out, careful inquiry should be made into the diet and the daily routine, and some idea of the child's temperament and mental attitude should be gained by observation of his behaviour. One must admit that in a certain number of children no precise cause of the anorexia can be discovered, but it is usually possible to place the case into one of three classes: (1) Cases in which the loss of appetite is due to the presence of some definite disease. (2) Cases where no sign of gross disease is found, in which anorexia is due to a temporary disturbance of the alimentary tract occasioned by errors of diet. (3) Cases in which refusal of food is a manifestation of neurosis.

Anorexia Resulting from Definite Disease.

It will be found that this class comprises a very small minority of the children who are brought for advice for this symptom. Nevertheless, cases are met with in whom the mother has noticed no other abnormality, but who show signs of disease at the time or shortly after. In these children there is usually obvious cachexia, which is not the case in the other classes which will be described. Scurvy, though not a common cause, may produce marked anorexia before any of the more typical symptoms have developed. In children of 3 years or more, tuberculosis, usually of thoracic or abdominal glands, is more likely to be found than any other disease. These children generally lose weight, but do not show any definite evidence of disease of the alimentary tract, and the tongue is usually clean. The treatment in this class of case must be directed against the underlying disease rather than against the symptom. Tuberculous children usually recover their appetite after they have been sent away to the country or on the balcony of a hospital ward. Cod-liver oil and malt are generally well taken, and serve to maintain nutrition until the desire for food is normal.

Anorexia due to Temporary Disturbances.

Anorexia due to temporary disturbance of the alimentary tract is occasioned by errors of diet in by far the largest number of cases; the great majority of the cases occurring between the ages of 2 and 6 are attributable to this cause. Some dyspepsia may be present, but it is usually not severe, and has often passed off, perhaps as a result of the abstinence from food, before the child is brought up for advice. The mother states that the child "picks at" his food, and refuses to continue his meal after a few mouthfuls have been eaten. The child is usually fairly well nourished, but looks out of sorts and is fretful and irritable. The tongue is pale, with slight furring

of the posterior part, but is not usually decidedly "dirty" unless constipation is present as well. There may be some vague discomfort on pressure in the abdomen, otherwise examination reveals no abnormality.

Careful inquiry into the diet of these children nearly always brings to light some unsatisfactory element in the composition of the diet or the arrangement of the meals. A certain number of them have been frankly overfed, and in them the anorexia is merely an expression of the need for alimentary rest. They should not be pressed to eat, but should have a small allowance of concentrated forms of food, and should not have more than half to three-quarters of a pint of milk in the day; they usually make a good recovery in two or three weeks. In a number of others the trouble will be found to have arisen from habitual irregularity, hurried meals at odd hours, supplemented by pickings from the parents' table, and biscuits or sweets at all times of the day. Correction of such obvious errors as these generally brings about a gradual return of the appetite. But in the majority of cases the dietetic error is qualitative, and this is especially so in the most severe and obstinate ones. It may take almost any form, but the first place can certainly be given to a sloppy diet containing excess of carbohydrate: a dinner of which the most frequent item is a mash of gravy and potato, probably followed by a milk pudding almost every day, and a breakfast or supper consisting largely of hot bread-and-milk. A diet such as this, relatively poor in protein and definitely deficient in fat, consumed readily with little need for mastication, is an extraordinarily constant feature of the histories given by the parents of this type of patient. It is in most cases well tolerated for a considerable time, and gives rise to no signs of malnutrition, but eventually the child begins to lose appetite, and perhaps to complain of vague dyspeptic pains. At this stage some Parrish's food or other iron tonic is obtained, and this never fails to aggravate the trouble. Finally, it is found that the child is losing weight, and advice is sought.

Cases of this type respond to treatment more readily than those of the two other classes; if the intelligent coöperation of the mother is obtained, one may be fairly confident of restoring the appetite in all but a few of them in a few weeks. The treatment demands a certain amount of attention to detail, and may be considered under the headings of management, diet, and drugs.

Management.—It is most important that a child's meals should be unaccompanied by anxiety, the effect of which upon the appetite is well known to most people by personal experience, and may be attributed to inhibition of gastric secretion by increased outflow of adrenalin. An unpunctual breakfast, eaten hurriedly and in apprehension of penalties for late arrival at school, is a situation which must never be permitted. The initiative in discovering this situation will rest with the medical adviser, for the information is not likely to be volunteered. Regular meal-times must be observed, and no food allowed at other times. It is well to make sure that the child is getting an adequate amount of exercise in the open air. Constipation is common, though by no means constant, and should of course be corrected when present.

Diet.—The diet must be regulated according to the age of the child. Slops, such as bread soaked in milk, or gravy and potato, should be forbidden altogether, and it is best to withhold potato in any form until the appetite has returned. Milk puddings should be restricted to two or three in the week, and replaced by baked apple, stewed fruit, and an occasional steamed pudding. Benefit often follows reduction of the daily allowance of milk to 1 or 1½ pints. The principal constituents of the diet should be eggs, in any form; fish, meat, fat bacon, with beans, peas, lentils, or green vegetables.

Porridge is a useful alternative for breakfast unless the child strongly objects to it: in hospital practice it is best to secure a good trial for it because of its

cheapness. Bread-and-butter may be taken, but in moderation, and *after* the more essential constituents of the meal.

Drugs.—In this type of case drugs are usually of considerable benefit, but harm is often done by unsuitable ones. Iron tonics are contra-indicated in all cases while the anorexia persists; they may be used later if the tongue is of normal appearance, but are not really needed even then. Cod-liver oil may do good to some children, but it certainly upsets others, and should be reserved for the few cases in which nutrition has suffered severely. An alkaline mixture containing sod. bicarb., gr. v.–viii., with infusion of gentian, rhubarb, and ginger roots, made up in peppermint water, is almost always of value at the onset. To this may be added tinc. aloes, ℥ v.–x., if required. The mixture should be taken 15 minutes before meals. Patent foods and medicines, particularly those containing malt, should be stopped.

Anorexia as a Manifestation of Neurosis.

Refusal of food as a manifestation of neurosis is found more often among the children of well-to-do parents, and the features which it presents vary to some extent with the age of the child. As a general rule, the older the child the more definitely psychopathic are the characteristics of his behaviour. In quite small children anorexia occurs as a form of mere "naughtiness" or negativism, often produced, and generally aggravated, by unwise management. The child usually shows signs of nervous excitability or spasmophilia, but under suitable conditions may develop into a perfectly normal child. The majority of these cases occur at a rather later age, between 5 and 10, and the neurosis has many points in common with other neurotic symptoms, particularly enuresis; in both cases it serves as a means of obtaining attention and exerting power for a child who has failed to do so in other ways. Anorexia and enuresis are not found to occur in the same child, but in dissimilar types, probably determined by the endocrine pattern. The child is usually fairly well nourished, but does not look robust, and the tongue is clean. The mother states that the child scarcely takes any food, usually refusing solid food from the very beginning of a meal, sometimes taking milk or tea fairly readily. If the child is forced to eat, the food may be vomited almost immediately afterwards. There is some loss of weight, but generally surprisingly little. It is nearly always found that as a means of exerting power this symptom has been entirely successful: the mother has devoted a large part of her time to coaxing and entreating, or to equally futile punishment.

Drugs have no place in the treatment of this type of case. The trouble will persist as long as his object is being achieved, and the essential part of the treatment is the removal of all signs of anxiety on the part of the parents. The medical attendant should be careful not to discuss the subject in the child's presence. The mother and nurse must be persuaded to stop coaxing and to make no comment on the appetite. If this is really carried out, a certain number of the patients will regain their appetite in a short time. But success on these lines is not obtained in every case. A large proportion of the parents are of an emotional type, and do not succeed in concealing their anxiety; moreover, a child who has borne the pageant of an empty stomach successfully from home to the seaside and to relations in the country will not always accept a sudden change of attitude. In many cases it is necessary to remove the child from home to the care of someone who will adopt the desired attitude from the start. If there is serious loss of weight hypnotic suggestion may be employed, and is usually successful, but relapse is likely unless the environmental conditions are dealt with at the same time.

SPIROCHÆTAL JAUNDICE.

REPORT OF A SMALL EPIDEMIC.

By D. M. LYON, M.D., D.Sc. EDIN.,

PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE,
UNIVERSITY OF EDINBURGH; PHYSICIAN, ROYAL
INFIRMARY, EDINBURGH.

With Microscopical and Experimental Observations by

G. BUCHANAN, M.B., D.P.H. EDIN.,

ASSISTANT CLINICAL PATHOLOGIST, ROYAL INFIRMARY,
EDINBURGH.

DURING the months of July, August, and September last there occurred in Edinburgh a small outbreak of infective jaundice which has certain points worthy of being recorded. The household primarily involved consisted of nine persons, of whom four became affected. The first to fall ill was the youngest (Case B, aged 7). The second victim (Case C, aged 13) began to complain about three weeks later. Case D, aged 17, took to bed four days after this, and Case E, aged 19, after a further interval of four days. One boy, aged 15, was unaffected, as also were the parents and the two maids. Three children in a second household also suffered, the earliest sign of the disease being noticed in Case F (aged 3, a playmate of Case B), about the same day as Case C took ill (August 8th). Cases G, aged 6, and H, aged 10, were noticed to be infected respectively 31 and 27 days after Case F.

On the appearance of jaundice in a second member of the first family the nature of the condition was suspected. The presence of spirochaetes in the urine was confirmed and a possible source of infection was looked for. These investigations proved negative. It was then recalled that a short time previous to the outbreak of the epidemic a small child (Case A) from the tropics (Tumpat, Kelantan, Malay Peninsula) had lived in the house for a week and had played a great deal with Case B. This subject is believed to have been the source of infection.

Details of Cases.

CASE A.—Female, aged 5, recently returned from the tropics, had apparently been ailing a good deal during the voyage. During the time she stayed in the house she seemed to be out of sorts, and was said to show slight jaundice even though she had a rather tanned skin. An evening temperature of 100° to 102° F. was recorded on several occasions. This child left Edinburgh for Wales a short time before the epidemic started. When spirochaetosis was suspected, the local public health authorities were communicated with and a sample of urine was obtained from the patient. This contained undoubted spirochaetes.

CASE B, a well-conditioned boy of 7, became ill on July 10th about a week after the departure of Case A. The patient became sick and had some diarrhoea, and his temperature reached 102° F. By Saturday, July 14th, he had sufficiently recovered to attend a Sunday school party, but on Monday, 16th, sickness and diarrhoea began again and he vomited all his food. No jaundice was noticed at this time. After about three days the child improved greatly, and appeared well for about a week, when a relapse took place. He was seen by Dr. John Thomson on July 24th. Pain was complained of about an hour after every meal, and the patient vomited even milk, although he complained of being hungry. The abdomen was normal, and there was no increased tension in the recti. A heavy blanket over the upper abdomen or pressure in this region elicited tenderness. The tongue was red and furred, and constipation was marked. The temperature was normal, but had been 99° on the evening of the 23rd; pulse 68, with respiratory irregularity. The presence of jaundice could not be definitely determined. On July 26th his general condition seemed to have greatly improved, but he vomited again. After three days' further illness, jaundice appeared suddenly and developed rapidly during 24 hours. The pigmentation varied from day to day, and traces were still present on August 13th. Spirochaetes were found in the urine when the patient was first seen—that is, on the thirty-fourth day of his illness. The condition in this subject proved to be mild, and convalescence was uneventful.

CASE C was a boy of 13. This patient began to complain greatly of headache on August 7th. Nausea and vomiting appeared on the same day, and there were also severe pains in the legs. Jaundice developed first on the 11th, and at this time the temperature was 102° F. When seen on the 13th the patient was lying listlessly in bed greatly prostrated. The skin had now a deep yellow colour. No spots were present and there was no itching. Both spleen and liver were slightly enlarged, the spleen reaching half an inch in front of the anterior axillary line, while the liver edge extended an inch and a half below the costal margin in the mid-clavicular line. There was slight tenderness of the liver. The abdomen appeared scaphoid. Constipation was marked, and the urine had a dark brownish colour from the presence of bile. On the 14th the patient seemed to be somewhat better. The blood was examined for spirochaetes, but none were found. Jaundice gradually increased for several days, then fluctuated from day to day. A few shotty glands appeared in the groin. On the 16th numerous pin-point hæmorrhages were noticed over the skin of the arms and the abdomen, and the soft palate showed a crop of rather larger hæmorrhagic effusions, the average size being about a quarter of an inch in diameter. Ten cubic centimetres of anti-spirochætal serum (B., W., and Co.) were given on the 16th and a similar dose on the 17th. No noticeable reaction occurred. The patient's condition improved rapidly. The lethargy present during the earlier phases of the disease passed off, the patient's appetite became ravenous after the 17th, and he got out of bed several times without permission. Further progress was uninterrupted.

CASE D was of more severe type. The patient, a girl of 17, was quite well until the evening of August 11th, when she felt out of sorts. Next morning there was considerable headache, accompanied by sickness and vomiting and also by generalised pains most severe over the lumbo-sacral region and the lower abdomen. (The sensations resembled the onset of menstruation.) During the 12th, 13th, and 14th the temperature ranged from 100° to 102° F., and the pulse ran about 96. The patient was bright and cheerful. There was no jaundice, and no hepatic tenderness could be made out. Albuminose appeared in the urine, but the only evidence of bile was a positive response to Hay's surface-tension test for bile acids (sulphur granules). On the 15th the patient became very prostrate, the abdominal pains were still severe, and there was no sign of menstruation. A faintish yellow tinge now appeared on the nose and the conjunctivæ. The liver edge could now be made out half an inch below the costal margin in the mid-clavicular line. The patient appeared to be distinctly worse on the 16th. She slept badly. Sickness developed and the patient vomited all food taken. Streaks of blood were present in the material returned from the stomach. The upper part of the abdomen was tender as well as the lower region. Numerous small petechiæ appeared on the arms. Ten cubic centimetres of anti-spirochætal serum were given intravenously. The temperature, which had been high before the injection, now fell to 97.8° and remained normal until the 24th. During the 17th the anorexia and vomiting continued. The patient became very restless and irritable, and she scarcely slept. Various measures directed to relieving the vomiting failed. It was impossible to feed by mouth as the vomiting was so frequent. A second dose of serum was given on the 17th. The condition remained much the same during the 18th. On the evening of that day quite a large hæmatemesis took place, and as the patient was still very restless and distressed and had not slept, morphia was administered. The patient passed a quieter night, being less restless and sleeping in snatches. No feeding was attempted by the mouth though the persistent retching had now stopped; nutrients and salines were given by rectum. During the day (19th) the patient remained semi-conscious, but rubbed her face a great deal. In the evening a definite gumboil developed on the right side of the lower jaw. The patient, though semi-conscious, became restless, angry, and distressed. The jaw swelling was lanced deeply without pus being reached. The mass apparently contained blood only. During the 20th, 21st, and 22nd the patient remained unconscious, showing a great deal of restlessness and irritability, from time to time calling out in delirious fashion. The legs and lower part of the body were frequently thrown about as if some pelvic irritation were present. Nutrients were well retained, and there was no sign of rectal trouble. Catheter specimens of urine showed the presence of blood, often in considerable amount. Menstruation became established on the 21st.

On the 22nd the swelling over the jaw became larger and softer, and was again incised, but no pus appeared even when the offending carious tooth was extracted. A considerable amount of oozing of blood followed the free incision of the swelling, and for several days very foetid blood-clot and necrotic material were evacuated from the area. A daily elevation of temperature from August 24th to

Sept. 3rd was attributed to absorption of toxic material from the mouth. Complete consciousness returned on the 23rd, a few hours after the second lancing of the gumboil. The jaundice continued to advance until about the 25th and thereafter slowly declined, being practically cleared up by Sept. 8th. By the 26th the patient had greatly improved, and her appetite was extremely good. In spite of the toxæmia the patient's general condition made rapid progress, and she was able to go on holiday on Sept. 8th.

CASE E, a girl of 19, felt rather out of sorts on August 13th. Next morning she did not complain, but by the evening her temperature was 101.8° F. Fever persisted during the 15th and 16th, but the patient felt better, took her food well, and had no pains. Traces of bile appeared in the urine on the 16th, and the patient was given 10 c.cm. of anti-spirochætal serum intravenously. A further dose was given next day and no immediate reaction took place. The temperature fell to normal after the second dose of serum, and remained about normal thereafter. A few urticarial spots were present on the arms from the 24th to the 27th. Anorexia, sickness, and vomiting began on the afternoon of the 18th, and for four days rectal feeding was required. The appetite returned on the 22nd. The advance and decline of the jaundice paralleled Case D. Further progress was uneventful.

Cases F, G, and H occurred in another family.

CASE F, a girl of 3, was a playmate of Case B. She had only a mild attack and was in bed for two days, August 8th and 9th, when she felt a little off colour. Thereafter she was quite cheerful and bright, although vomiting occasionally took place. Jaundice appeared on August 15th, and spirochaetes were demonstrated in the urine on the 16th. Her nose bled a few times, and a crop of hæmorrhagic spots appeared on the palate. No blood was seen in the urine or the vomited matter.

CASE G, brother of F, was aged 6. He first became unwell on Sept. 8th, but was never very ill. Sickness, though troublesome, was never serious. Jaundice appeared on Sept. 12th and some epistaxis occurred.

CASE H, a girl of 10, fell ill on Sept. 4th. This subject had a much more severe attack than either F or G, the main feature being excessive vomiting. Epistaxis was also present in this case, but no gross bleeding occurred elsewhere. This patient was confined to bed for about a fortnight.

Cases F, G, and H recovered fairly quickly in direct ratio to the severity of the disease, which, it will be noticed, was proportionate to the age of the patient.

The cases outlined above answer the usual description of spirochætal jaundice. Considerable difference in severity was noticed as is common in such epidemics. In nearly all the victims the illness commenced suddenly, like the onset of an infectious fever, the initial pyrexia being accompanied by malaise, headache, and various pains. The most pronounced symptoms were gastro-intestinal disturbances, jaundice, and hæmorrhages. Nausea, anorexia, sickness, and vomiting were present in all subjects. The combination of distaste for food and the tendency to vomit everything eaten made feeding difficult in the more severe cases. Acidosis occurs readily in children, and acetonuria has been noted as a common symptom in this disease, so in order to avoid this risk a special endeavour was made in Cases D and E to maintain nourishment by nutrient enemata containing large quantities of glucose (as advocated by Ryle). By this means it was possible to prevent the appearance of more than the merest trace of acetonuria on one or two days. Constipation was troublesome and required constant attention. The rapid return of appetite when convalescence became established was a striking feature in several of the subjects. Jaundice occurred in every case, being marked in all except the mildest. As has been pointed out, it does not come on until the fever has been present for about four or five days. It may then develop very rapidly during a few hours, increasing in intensity for several days and then disappearing slowly. In cases seen early, bile could be detected in the urine before it was apparent even in the conjunctivæ. Irritation of the skin was scarcely complained of. The pulse-rate was usually elevated during the febrile phase, and later a certain amount of slowing occurred in some of the cases. The hæmorrhagic character of the disease was prominent

in this epidemic. Petechiæ and larger skin effusions were frequently noted, and blotchy patches were found on the palate in two cases. Epistaxis was common. In three of the subjects red blood corpuscles were found in the urine, while in one of these cases considerable hæmorrhage occurred from the urinary tract. The vomitus brought up after distressing retching often contained streaks of blood. Case D had a rather severe hæmatemesis. Muscular pains and abdominal tenderness were present in the more severe cases, and in these there were also some temporary enlargement and tenderness of the liver. The urines throughout were strongly acid, bile was present in large quantity, traces of albumin were found in several during the febrile period, while the urines of C, D, and E showed for a time considerable albumose.

The anti-spirochætal serum employed was prepared from a strain of organisms isolated from rats caught in East Lothian. Two doses of 10 c.cm. each were given on successive days to Cases C, D, and E. In each subject the temperature fell to normal and remained there. No other immediate effect was noticeable. It is hardly likely that the sickness could be attributed to the serum. About ten days after the intravenous administration of the serum an urticarial rash appeared on the forearm in the neighbourhood of the site of injection in two cases.

The mental symptoms of Case D were difficult to account for. Breathlessness, mental confusion, and unconsciousness are usually recognised as prognostic signs of very grave import, and at one time this subject was so low that her life was despaired of.

MICROSCOPICAL AND EXPERIMENTAL OBSERVATIONS. BY DR. BUCHANAN.

As such an outbreak of this disease in two families in a town has not been reported in this country before, every effort was made to confirm the clinical diagnosis and to investigate all possible sources of infection. There was no difficulty in arriving at the diagnosis of infectious jaundice on clinical grounds, but confirmation of this by laboratory means was not so readily attained. The confirmatory methods adopted consisted in the examination of the blood and urine. As the blood is considered to be infective up to the seventh day of illness, specimens were taken only from those patients seen during the first week of the disease. Several films of the blood were examined by dark-ground illumination, and about 4 c.cm. were inoculated intraperitoneally into guinea-pigs. Although spirochætes are not eliminated in the urine until about the eleventh day, for statistical reasons, specimens were examined throughout the illness when circumstances permitted. Films of the centrifugised deposit were examined by dark-ground illumination, stained films were prepared, and about 4 c.cm. of urine with deposit were inoculated intraperitoneally into guinea-pigs and occasionally mice. It so happened that only three of the patients were seen within the period when blood examination and animal inoculation might have proved successful; the findings, however, were negative.

The results of the microscopic examination of the urines after the febrile period, though positive, were not unequivocal. Although spirochætes were found in the urine of all the patients at one time or another they appeared to be devitalised and degenerated. An explanation of this may be found in the acid reaction of the urine and the presence of bile in it, for experiments showed that these properties were not only inimical to the vitality of the leptospira but also destructive to its characteristic morphology. Hence a difficulty arose in establishing a diagnosis on microscopic examination of the urine alone. In two of the patients—viz., D and E—seen from the onset of illness, specimens of urine were frequently examined to ascertain the day on which spirochætes first appeared in the urine. Definite, though few, spirochætes were first found on the fourteenth day in Case D, and on the twelfth day in Case E. In the other cases circumstances only permitted of obtaining the first specimen of urine at varying dates after the acute stage.

Spirochætes were noticed in each case from the eighteenth up to the twenty-third day of illness. With the exception of Case E, spirochætes were not observed in the urine after the thirty-seventh day. In each instance spirochætes were detected as a rule with difficulty; exceptionally three or four might be encountered in one microscopic field and none on further examination of the slide. By dark-ground illumination the fine spirals were not recognised, but they seem to be indicated by a slight granular appearance, which was more pronounced in the stained films. The forms seen could only be regarded with suspicion as of the leptospiral type, so that it remained to rely on the results of animal inoculation for confirmation. Repeated failure to produce by this means any signs or symptoms of the disease in animals prevailed over a long period and necessitated the use of a large number of animals. The devitalising effect on the leptospira of the acid and bile in the urine was held partly responsible for the failure to infect. Although bile ceased to be excreted in the urine after a time the reaction remained strongly acid. Forty-four animals, including four mice, were employed before absolute confirmation of the clinical diagnosis was obtained. Thirty-one of these animals remained alive and well and 13 died; the latter number comprised 11 guinea-pigs and 2 mice. The results of the animal inoculations with the urines obtained at different periods during the course of the illness may be tabulated as follows:—

Table Showing Results of Animal Inoculations,
with Urine of Patients.

Case.	Animals inoculated.	Result.		Post-mortem findings.
		Survived.	Died.	
A	2	2	0	—
B	5	5	0	—
C	6	5	1	Lungs showed spotted hæmorrhages; no jaundice; no spirochætes found. Sub-inoculation negative.
D	11	9	2	<i>B. coli</i> infection arising from urine inoculated.
E	11	6	5	One showed typical spirochætal jaundice with leptospiras present in the organs. Sub-inoculations positive in 7-9 days. One guinea-pig and one mouse showed spotted lung hæmorrhages, but no leptospiras found. Subinoculations negative. Two showed no obvious lesions.
F	2	1	1	Lungs showed spotted hæmorrhages; no leptospiras found.
G	4	1	3	Two showed lung hæmorrhages, one typically spotted, the other more diffuse. No leptospiras found. One mouse showed no lesions or leptospiras.
H	3	2	1	One lung showed a prominent hæmorrhagic spot on anterior aspect. No leptospiras found.

The outstanding feature in the table is the record of only one definitely positive result out of 44 animal experiments. Seven animals no doubt showed localised lung hæmorrhages peculiar to leptospiral infection, but as the organism was not recovered a definite diagnosis could not be made.

Noteworthy observations are associated with the urine obtained from Case E, and with the infected animal. Spirochætes were found in the urine of this patient on six different occasions and up to the sixty-sixth day from the onset of illness. Examination of the urine on the sixty-sixth day revealed the presence of only a few spirochætes, and the animal inoculated with this specimen succumbed in 30 days with signs of typical spirochætosis. The fatal issue was singularly postponed, but the paucity of the spirochætes in the urine, amongst other factors, may be a cause of this; inoculation of infinitesimal doses of culture may not prove fatal until about the twenty-ninth day. Sub-inoculations into other guinea-pigs from the originally infected animal have given very irregular results, pointing either to variability in the selective action of

this strain of leptospira, or to individual idiosyncrasies in the animals inoculated. In the third animal passage both jaundice and skin hæmorrhages were absent, but the lungs were typically mottled; spirochætes were found with difficulty in the liver. In the fourth animal passage the only macroscopic lesion was confined to the uterus, the whole of which presented the appearance of a bicornuate blood-clot. But for this lesion the animal showed no naked-eye evidence of infection. Here again spirochætes were extremely few in the liver or other organs, and none were found in the uterine blood. These facts are mentioned merely to indicate the peculiar behaviour in animals of this human strain. So far the passage of local rat strains through guinea-pigs has given, as a rule, more uniform results.

The investigation of a possible source of infection included the examination of rats and mice, the house cat, cistern and tap water, and finally a specimen of urine from Case A. No rats or mice had ever been seen in the house in question and the efforts of an expert rat-catcher failed to trap any in the house or garden. Three rats and two mice caught at some distance from the infected house showed no evidence of leptospiral infection, and animal inoculation of kidney emulsion and urine proved negative in each instance. The house cat fell under suspicion on account of illness, but as a carrier it was definitely excluded. Water from the cistern and from the taps in the house and garden was examined. Nothing of a suspicious character was found, and animal inoculations with several samples from these sources were negative. At a later visit to the house mention was made of a child visitor, Case A, from the Malay Peninsula, in July. It was recalled that Case B fell ill about a week after the departure of the visitor to Wales, and it was mentioned that the visitor had not only been ill during the voyage, but also slightly indisposed on the visit. Hence it was thought advisable to try to get a specimen of blood for serological tests and a sample of urine if possible. Dr. W. T. Benson, assistant medical officer of health, was advised and he communicated with the local public health authorities in Wales. A specimen of urine only was received early in August. Dark-ground examination revealed a few non-motile spirochætal forms presenting a granular appearance. Stained films confirmed the presence of undoubted spirochætes, but here again we could only say that they were suspiciously like leptospiral organisms. The urine gave no bile reaction but was distinctly acid. Two animals were inoculated; both remained alive and well. The results of this part of the investigation throw suspicion only on Case A. Since this outbreak the rat question locally has been most extensively studied, and the findings indicate that this agency cannot entirely be ignored. No rats, however, have so far been caught in this residential district, and the existing conditions make this source highly improbable. We are therefore of the opinion that the more likely source of infection in this outbreak was the visitor from a part of the tropics where the occurrence of leptospiral infections has already been recorded.

COMMENTS ON THE FINDINGS.

The investigation has disclosed certain notable features. Although blood was obtained from two cases on the fourth day and from another on the seventh day of illness, both direct examination and animal inoculations of the blood were negative. The failure to infect guinea-pigs inoculated at this stage is not in accordance with the results of other observers; personal experience has proved, however, that some guinea-pigs are insusceptible. Diagnosis by direct blood examination has not succeeded in any case so far. Inada found that spirochætes were usually few and difficult to detect in the blood and reported their presence in only two out of a hundred cases.

A definite diagnosis by urinary examination and animal inoculation in these as well as other cases has constantly presented difficulties, attributed partly to the reasons already mentioned. These reasons

may account for the difficulty in infecting animals, but apparently did not apply to human infection in this outbreak. The infectivity of the spirochætes may depend on the period of time they remain influenced by the destructive action of acid and bile in the urine before experiments are performed. Previous investigators have observed that two-thirds of positive urines, some with many spirochætes, failed to infect guinea-pigs. One particular urine from a case in the writer's own experience contained degenerated and granular spirochætes in masses, but inoculation failed to infect in six animals; this urine was very acid and gave a marked bile reaction.

Another notable finding was the presence of spirochætes in the urine of Case E up to the sixty-sixth day. This is unusual, as the Japanese workers observed that the spirochætes invariably disappear completely from the urine after the fortieth day. In one instance, however, they reported the presence of spirochætes up to the sixty-third day. In view of these exceptions, therefore, the visitor from abroad may be considered another instance in which the elimination of spirochætes was singularly prolonged. Subsequent events point to Case B as the probable infective agent in four of the patients—viz., C, D, E, and F. This probability is based on the possible infectivity of the urine over a certain interval. Three members of one family and one child of the other became ill on different days in the same week, and from 27 to 31 days after Case B fell ill. As the incubation period appears to be between six to eight days the period of invasion would thus coincide with the interval between the nineteenth and twenty-third day of illness in Case B. Although the urine of this patient was not examined then, it is highly probable that spirochætes were present, as they were found on the thirty-fourth day of illness. The two families affected lived not far distant from each other, which allowed the two youngest members of each family to play frequently together. It is a remarkable fact that in this second household an interval of 27 to 30 days again elapsed before the older brother and sister of Case F became ill. Spirochætes were found in the urine of Case F on the eighteenth day. Such a course of events suggests infection by contact with human cases and the agency of spread points to the urine. The path of invasion was not manifest, although distinct palatal hæmorrhages in one case may have some significance in this respect. The spread of spirochætal jaundice by contact with human cases is considered most unusual; the urinary findings indicate a possible reason for this, but the history of this outbreak tends to indicate that such a mode of spread is liable to occur. In Japan cases have been noted in several members of a family, but those affected became ill at the same time or at an interval of one to two days. The source and mode of infection in such cases was not known.

We desire to thank the Committee of the Royal College of Physicians' (Edinburgh) Laboratory for the facilities afforded in carrying out this investigation, and the Medical Research Council for pecuniary assistance.

NEW CHILDREN'S WARDS AT NORWICH.—H.R.H.

Prince Henry has laid the foundation-stone of a new children's block at the Norfolk and Norwich Hospital. There will be five wards containing a total of 30 beds, and plate-glass partitions will enable any one of the divisions to be immediately isolated. The whole of the south side of the wards will be made to open, to facilitate open-air treatment. The block is being paid for with a donation of £10,000 from Mr. Lane, of Swaffham, and Mr. Simpson, of Sheringham.

FREEMASONS' HOSPITAL.—The £120,000 needed for the endowment fund have now been secured, but during the past year expenditure exceeded income by £2579. More beds have been provided and an extension will shortly be necessary—the waiting list is always considerable, and the hospital is at present practically confined to surgical cases. In the last 12 months 171 additions have been made to the list of Founding Lodges, but Dec. 31st next is to be the latest date at which a lodge can become a Founding Lodge.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

(Continued from p. 457.)

BEFORE coming to the evidence of the Controller of Insurance in regard to the Approved Societies and the evidence of the societies themselves, we give hereunder a short summary of the official evidence given by the representatives of the Ministry of Health in regard to Medical Certification and the duties of the Regional Medical Staff, both of which subjects bring the insurance practitioners into indirect relationship with the Approved Societies.

Medical Certification.

(Q. 1208-13 and App. C. 50-70.) The provision of medical certificates, to enable the insured person to claim during illness payments which are known as sickness and disablement benefits, is part of the contract with the doctor covered by the general capitation fee. He is required under the rules to certify that a patient is incapable of work by reason of some specific disease or mental or bodily disablement. The cause of incapacity is to be stated as precisely as his knowledge of the patient permits. There are separate forms for first, intermediate, and final certificates, and for those to be given in cases of chronic illness and of convalescence, and in other special circumstances. Where practicable, the certificate must be given to the patient at the time of examination, and in other cases the certificate must be sent or given to the patient within 24 hours of the time of examination.

Asked whether the arrangements are working satisfactorily Dr. Smith Whitaker said:—

(Q. 1210.) I think, so far as the Department are concerned, they are working as satisfactorily as you could expect any system to work, having regard to the difficulties of the conditions we have to deal with. So far as the doctors or the societies are concerned, I do not think one could say that they are entirely satisfied with the arrangements. The doctors complain that they have found the arrangements irksome, but I think that both with them and with the societies the difficulty arises from the fact that they have not appreciated the necessity for the restrictions; and in some cases society officials who have not appreciated the importance of carrying the system out thoroughly have, through their insured members, pressed the doctors to give certificates in a way that is irregular.

In the proceedings before the Court of Inquiry into medical remuneration last year, there were complaints by societies in general terms that doctors gave certificates too readily, but otherwise there are not many such complaints, because a society that is dissatisfied with a doctor's certificate refers the case to one of the regional officers to get the question of incapacity tested. There is a certain amount of vagueness observed on occasions in the description of the cause of incapacity, but there are not many complaints received from societies on the ground of inadequate description. Complaints from an insured person that he has been refused a certificate are rare. Certificates from a non-panel doctor will be accepted by societies.

(Q. 1260.) One of the commonest causes of trouble with the doctors arises from the fact that an insured person does not ask for a certificate at the proper time and is faced with a difficulty later on when he realises that he has a claim to make against his society for sickness benefit. A doctor's certificate must relate to an examination made at the time of giving the certificate and not to some previous occasion. The difficulty may be met by the doctor

giving a "voluntary" certificate and forms for this purpose are provided.

(Q. 261-3.) The function of the certificate from the point of view of the society is to enable them to be satisfied that the insured person is incapable of work. The decision is the society's and not the doctor's.

Meaning of "Incapable of Work."

(Q. 295.) The Controller, in his earlier evidence, was asked how the phrase "incapable of work" is, in fact, interpreted under the guidance of the Ministry by the Approved Societies. He said that the rule now generally recognised is that in the earlier stages of an illness the insured person should be totally incapable of following his own occupation. If after a certain time it appears to the society that a member will never be able to resume his own occupation, the society must then apply its mind to the question whether the person is incapable of any other kind of work, and whether that work is available for that person.

(Q. 296.) Could it be put like this . . . that in practice . . . "incapable of work" means physically incapable of doing work which in the circumstances at the moment could be regarded as reasonably open to the insured person?—That is a fair definition.

(Q. 297.) It comes very close to that?—Yes; but I think in the earlier stages it is limited and the society only looks at his normal occupation.

Twenty Million Weeks of Incapacity.

(Q. 273.) Elsewhere with regard to the working of the certification system, Sir Walter Kinnear said:—

I think with regard to the question of medical certification, speaking quite generally, and bearing in mind the fact that in England cash benefit is paid each year in respect of about 20,000,000 weeks, the medical certification system is working well.

The Regional Medical Staff.

(App. C. 170-175.) The Regional Medical Staff was appointed, primarily, to meet the need—which since the inception of medical benefit in January, 1913, had been repeatedly expressed by Approved Societies and by doctors—for a body of medical referees, who would advise in cases of doubtful incapacity for work, and also in cases of admitted incapacity in which it appeared that a second medical opinion might contribute to the restoration of the patient's working capacity. A whole-time staff of 33 Regional Medical Officers was established in 1920 for England and Wales, with 5 Divisional Medical Officers having supervisory functions. There are also certain part-time referees employed as occasion requires.

The duties of the Regional Medical Staff, in their capacity of referees, fall under the two heads of (a) advising in cases of doubt as to incapacity for work, and (b) advising on questions of diagnosis and treatment. References under either head may be made either by Approved Societies in respect of their members or by insurance practitioners in respect of insured persons under their care. The whole-time officers have other duties—e.g., the inspection of medical records and duties in connexion with excessive prescribing.

Number of Cases Referred.

The number of cases of doubtful incapacity referred in 1923 in England and Wales was 146,000. Of this number, in 60,000 the insured person failed to attend for examination, and, of the remainder, in 64,000 the patients were found to be incapable of work and in 22,000 not incapable.

(Q. 1298.) The numbers give the impression that quite a large proportion of the patients on being told to go to the referee at once declare off rather than face an ordeal in which they have reason to think they will be found out. It was suggested to the witnesses that there might be some explanation in the way of delay by the societies in referring the cases. As to this, the witnesses said:—

In a batch of cases in which inquiry was made . . . we found that out of 2600 cases in a 12-month period about

* In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247-8); The Provision of Medical Benefit (Feb. 7th, pp. 301-3; Feb. 14th, pp. 355-6; Feb. 21st, pp. 403-5); Financial Provisions of the Act (Feb. 28th, pp. 454-7). References to the official statement which has been issued as an appendix in four sections are given thus: Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

17 per cent. had declared off before they received our notice that they had been referred, and about 7 or 8 per cent. were unfit to attend. The total number of those who did not attend for examination was 46 per cent. That leaves 21 per cent. [i.e., 46-25] not accounted for by those two facts. Of the 21 per cent. a considerable proportion . . . were people who were on the point of declaring off or were nearly well and went back to work rather than have the trouble of facing an examination, or because they felt quite sure what the result of the examination must be.

There are also undoubtedly some cases where persons will forfeit their benefit rather than face an examination by referees.

(Q. 1472.) As to the cost of the system, the Approved Societies make a direct contribution of a fee of 1s. 8d. for each examination and also bear the cost of the part-time referees and other expenses which are specially attributable to the reference side of the work. That includes the cost of travelling expenses of insured persons, the cost of fees of nurses, and the rent of premises used exclusively for examination.

Referee Work and Certification in Scotland.

(App. II. C. 43.) In Scotland five District Medical Officers—corresponding with Regional Medical Officers in England—were appointed in 1921. Arrangements were also made for medical inspection rooms at two local centres in hospitals, infirmaries, &c., situated in other parts of the country. The extreme north of Scotland and other remote areas were excluded from the scheme owing to their insured population being so widely scattered. Examination of cases is sometimes undertaken in these excluded areas by a member of the Board's headquarters staff in conjunction with other business, special journeys and expenses being thus avoided.

(Q. 2017-8.) As to certification generally in Scotland, Sir James Leishman said that the system is working fairly satisfactorily, but there is an underlying current of dissatisfaction with regard to certificates. The number of formal complaints from societies is small. When there is complaining in general terms about lax certification the Board direct the attention of societies to the fact that they have a three-fifths representation on Insurance Committees and that those are the proper authorities before whom complaints should be laid for formal investigation.

(To be continued.)

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

FURTHER SITTINGS.

(Continued from p. 405.)

THE sittings of the Commission were resumed on Feb. 24th, the chair being occupied by Mr. N. Micklem, K.C.

Before hearing evidence, a man who said he was a member of the Bar and sent up his name, asked for permission to give evidence, at a time convenient to the Commission, as to what took place behind the scenes. Mr. Micklem promised that after discussing the matter with Mr. Macmillan, the Chairman of the Commission, he would communicate with the applicant.

Evidence from the National Asylum Workers' Union.

Mr. Gibson, secretary of the National Asylum Workers' Union, with a membership of 11,000, tendered information on the Union's objects and the conditions of employment of those engaged in institutions for mental care. The Union's suggestions included the following: (1) The administration of the Lunacy laws, the care of the insane, and the coördination of research into the diseases which should be directed from a centre. Failing the complete nationalisation of mental hospitals, the Government

grant should be increased to 50 per cent. of the maintenance cost, conditional on the approval of the Board of Control. (2) Mental health authorities should have powers to inquire into the incidence of insanity in their own areas and to provide outdoor clinics in all mental hospitals under their control; also to organise such clinics in association with general hospitals. A lunacy rate should be leviable, and there should be power to commit patients for a time for treatment without their being certified. (3) There should be an end of mental hospitals run as profit-making institutions, as there were risks of grave abuse. (4) In many curable cases the certification as paupers had a detrimental effect on the patients. (5) The attention of medical men in institutions should be confined to medical affairs, though they might remain the acting disciplinary authority, and they should have the power of suspension only. (6) There should be a legal minimum proportion of medical officers and nurses, and 50 per cent. of the total nurses should be qualified mental nurses. He thought local authorities should be empowered to deal with incipient insanity, and to collaborate with the Board of Control in its work. Private mental hospitals, he said, were frequently changing their staffs, and but little effort was made to engage and retain qualified mental nurses, and the great safeguard of personal liberty, visitation by a publicly-elected committee, was not operative in them. In some mental hospitals the training given to the nurses was very casual. This was largely because the medical staff was too small to even attend adequately to the patients. In one institution with 600 patients there was only one assistant to the medical superintendent.

Answering Mr. Micklem, Mr. Gibson said that, speaking generally, the conditions were more satisfactory on the male nurse side than on the female side, and that few matrons were really satisfactory. On that side, too, there was a tendency to retain on duty officers who were too old for the work. In many mental institutions the patients were, in the witness's view, put to bed far too early—i.e., 7 to 7.30. If they were allowed to stay up longer he thought there would be less need for hypnotics.

Mr. Micklem questioned this witness and Miss Maud Wiese, a chief charge nurse at Claybury, on the subject of the employment of female nurses on the male side in mental institutions, and Mr. Gibson replied that he had yet to meet the medical superintendent who would allow his own wife or daughter to nurse in a male mental ward. Generally speaking, asylum workers regarded the practice as objectionable, especially as 10 per cent. of all male cases of insanity were of syphilitic origin, and an even larger proportion were sexually abnormal. Female nursing in male mental wards was commoner in Scotland than in this country, and there, he contended, the effect upon the patients was disastrous. Miss Wiese declared that this work on the male side was very degrading and repulsive to women, and that they should not be required to do it. Generally, Mr. Gibson said, the relations between nurses and patients were, so far as he had seen, friendly.

Mr. Micklem asked Mr. Walter Blood, the President of the N.A.W.U., whether it was true, as had been alleged, that if patients incurred the displeasure of attendants, when the time came for the question of their discharge to be considered, the attendants concerned kept them back so that they were not seen by the visiting committees or doctors. Mr. Blood replied that he did not think that was possible; it certainly had never happened in his experience. Nurses were not consulted at all about the discharges. As soon as a patient showed reasonable improvement he was placed in the convalescent ward. Mr. Blood, in answer to a further question, said he had never known croton oil used. Occasionally a sleeping draught was given, but only in the night. Mr. Gibson said nowadays every dose of medicine, even an aperient, was prescribed and sent from the dispensary

labelled with the patient's name. If not used, it was returned to the store. It was possible for two patients to keep a whole ward awake, and sedatives were then required.

Questions of Cruel Treatment.

Mr. Gibson said that the mental nurse had to endure abuse and assault daily, and occasionally the tendency to retaliate overcame the will-power. This was not by any means common. The qualities required of the mental nurse were of the highest; tact, forbearance in the face of vile abuse, kindness even after savage assault, firmness and endurance. The hours at present operative were, he said, too long, and the wages too low. He compared the training and conditions of the general nurse with those of the mental nurse. He strongly urged the adoption of the three-shift system in mental hospitals, to ensure the fullest justice to the patients. Among other recommendations made by the body he represented were an improved dietary, and especially the provision of supper of a light character about 8 P.M.; better clothing and more outdoor recreation, such as bowls and tennis; also that the nurses' homes should be apart from the institution. There should be, in addition, it was suggested, an extension of the principle of single care.

In reply to questions Mr. Gibson said he thought the Board of Control should be strengthened; at present it had no directing authority over other bodies. If an institution did not satisfy the Board, the latter should have the power to withhold the grant. He did not think there should be an opportunity of profit-making out of a disease affecting the mind. He believed that frequently patients' friends paid at these institutions for services which were not rendered—e.g., though payment was made for a special nurse, it was easy to put the patient concerned into a general ward. The friends who made complaints usually did not desire to be personally implicated in an inquiry which might follow. A frequent cause of changes in staff was that the nurses got to know too much about the administration. He said he knew that some able medical men were very indifferent administrators.

In answer to Sir Humphry Rolleston, Mr. Gibson said the desire was that the outdoor clinics should be associated with both general and mental hospitals.

The Commission resumed its sittings on Wednesday, Feb. 25th, when Mr. H. P. Macmillan, the Chairman of the Commission, presided.

A Question of Procedure.

The Chairman intimated that in consequence of the experience already gone through in the case of the first of the six witnesses which the National Society for Lunacy Reform named it had become necessary to re-consider the Commission's procedure. Three days were devoted to Mr. Holman's case, on only one of which the witness attended, and complaint was made of the inconvenience he had experienced owing to his case having been gone into publicly, and the indisposition following his appearance and cross-examination compelled him to give up the fight. Moreover, it had been found that the procedure adopted created an atmosphere of controversy and recrimination which the Commission could not allow to recur, and they would not take the responsibility of permitting ex-patients to be exposed to the ordeal of public examination. Therefore in the remaining cases the Commissioners would themselves examine the witnesses in private, though the Chairman and counsel for the National Society tendering the witnesses would not be excluded from the inquiry.

Evidence of Dr. Montagu Lomax.

The Commission then proceeded to take evidence from Dr. Montagu Lomax, author of "The Experiences of an Asylum Doctor," a book which was published in 1922. He said his experiences had led him to the view that the present system stood in need of reform,

and if the kind of reform he hoped for were brought about the office of superintendent would be separated from that of the executive chief, as the latter interfered with his special medical activities. He agreed that some of his objections to the combination of medical and executive functions would disappear if large county mental hospitals were replaced by the modern villa asylum, with a limited number of inmates. He said he strongly recommended that cases sent into hospital by a medical man for treatment in the incipient stage should remain under his care while they were in the hospital, so that he might study them there and follow them up. He thought the inspections of visiting committees should be less formal than was at present the case, and, wherever that was possible, the visitors should be unaccompanied by members of the staff. His experience was that visiting committees hurried through the wards with an attendant, and said a few words to any who chose to speak to them, but were glad to get away again. It was little short of a farce. The matter was different when the visitor showed himself kindly disposed towards the patients, who were quick to discern it. Pressed by the Chairman for suggestions for bringing about improvement, Dr. Lomax said that special attention could be given to border-line cases, and visiting committees should set aside certain times for hearing complaints of patients; a kind of small appeal court. A classification of cases could be made beforehand, so that there need be no loss of time. He believed very few complaints of ill-treatment were made to the doctor. He would abolish the formal dinner to the visiting committee, a function which occupied a good deal of time, and militated against the serious purpose of the visit.

Lord Russell said that on his own visiting committee that was not so; the meal was not prolonged, and the time was occupied largely in a talk about the cases.

Dr. Lomax thought that all mental hospitals ought to be under the control of the Ministry of Health. Asked by Lord Russell whether he thought more frequent visits, such as fortnightly, would be a help, the witness said he did not think it would work, as the members of visiting committees had their own work to do. He strongly favoured the coöption of women on these committees. One woman visitor, at Hull, paid a visit to the asylum at 7 o'clock in the morning. She was kept waiting in a side room 25 to 30 minutes while preparations were hurriedly made for an inspection. He agreed with Mr. Gibson (who was examined shortly before) as to the need of a 48-hour week, but he had not the same view as to the value or adequacy of the nursing certificates to stamp nurses as efficient. Many of the subjects required in the schedule it was not necessary for nurses to know. He would have general hospital nurses with a special training in mental nursing. The possession of a certificate often made a nurse feel she was a very important person, and this detracted from her efficiency. The possession of some of the milk of human kindness was worth all the badges in the world.

The Chairman pointed out that it had long been urged that nurses should reach a certain standard of efficiency, and accordingly an Act was passed, and then it was said this was not a test for ascertaining whether a person had the real nursing vocation.

Dr. Lomax replied that experience showed it was not the nurses holding certificates who made the best nurses from the patients' point of view. And the examination itself deterred many people from entering the nursing profession. He would have entrants sign a contract to stay for at least a year or two. Much more supervision should be exercised so as to ascertain the characters of would-be nurses. Sometimes advertisements were seen for nurses who were not required to have had any previous experience. He would secure the right type of people by making the service more attractive, giving better pay, and shortening the working hours. Until recently the nurses had been

almost as much neglected as the patients. It was one of the hardest services in the world, and those engaged in it deserved the thanks of the community. They ought not, he thought, to be taught so much psychiatry, certainly not until the doctors themselves were more agreed about it. In some cases lectures to nurses were given by an attendant.

Alleged Ill-treatment of Patients.

The Chairman asked the witness whether, when he was an official in an asylum, he saw any cases of ill-treatment, under his own eyes, by an attendant, and the witness replied that he did not see any cases, and that a doctor never did—indeed, he was the last person in the world who would. He suspected ill-treatment in a few instances. He feared that in most instances of ill-treatment the patient was too cowed to make a complaint to the doctor or the superintendent, fearing what would happen to him at the hands of the attendant afterwards. Asked by the Chairman whether instances of ill-treatment while he was a doctor in an asylum would not be of more value than hearsay evidence of alleged cases years after leaving asylum service, the witness said he saw the Chairman's point, but while engaged in the work he did not suspect what he now believed went on in that way.

The Chairman said it was a serious allegation that attendants were cruel to patients.

Dr. Lomax said he was only giving experiences which had been related to him. He could not possibly prove these things; but he had patients to produce who would, if allowed, give first-hand evidence of the ill-treatment to which they had been subjected and which they had seen.

The Chairman said the Commission was satisfied that cases of cruelty, possibly of gross cruelty, did occur; they must inevitably happen, just as accidents might happen on the best administered railways in the world. The great point was as to how ill-treatment could be stopped, or at least diminished.

Answering Lord Russell as to what value the witness attached to statements of patients on this question, he said he attached the greatest value to them; it took him two years to convince himself that this cruelty went on. He thought that in every case the patients were telling the truth. They had, since leaving the mental institutions, lived sane lives.

In reply to Mr. Snell, he said his allegations as to cruelty must certainly be taken to include the female side. He asked that the Commission would hear not only ex-patients, but also ex-attendants. The remedy would not be found in the Commission's report, but by an aroused public opinion which would be expressed on a note of indignation, even horror, that these things could happen.

Ex-attendants to be Heard.

After the luncheon interval the Chairman said that his colleagues were impressed by the suggestion that one or two ex-patients and one or two ex-attendants should be examined, and invited Dr. Lomax to furnish names and addresses of such and they would be officially requested to attend.

Continuing his evidence, Dr. Lomax said there were hundreds, even thousands, of cases of cruelty in mental institutions, and the Chairman remarked that the making public of such a statement would have a most unhappy effect in many homes, probably deterring people from sending relatives to these institutions when they needed treatment. Dr. Lomax said he did not wish to convey that impression. Continuing, the witness said that in cases of ill-treatment it should not be optional on the asylums committees to ask for a prosecution; when there was evidence of such conduct there should be an obligation to place the case in the hands of the police.

Lord Russell asked whether the witness would have a prosecution undertaken when it was practically certain there would be no conviction, and the witness replied that the onus should be on the judicial

authority. He would be satisfied if, in a case deemed suitable for prosecution, all the papers were laid before the Public Prosecutor, leaving further decision and procedure in his hands.

Considerable argument followed on the question of alleged wrongful detention, the Chairman setting out the conditions of the harmless but certifiable person, and the witness said he favoured the boarding-out system as operative in Belgium, the patients being detained in such places as uncertified, so avoiding the stigma. He would have these patients remunerated for what they did.—Lord Russell said that in that case the trade-unions would have a word to say.—Dr. Lomax went on to say that when he was a doctor in Prestwich Asylum there were two or three inmates whom he considered sane, and he recommended their discharge, but no notice was taken of his recommendation. As soon as his book was published, however, two of them were discharged. He did not write about them to the Board of Control when he was in the asylum, and after he had left it was not his job.

The Chairman quoted from Dr. Lomax's book a passage in which the author spoke of a patient who had been in the asylum for a year and whom he considered sane, but as he deceived him, the doctor, he kept him back from discharge another two months as a punishment. The witness said it was a case of malingering, the man having obtained admission into the asylum to escape the clutches of the law. He was closely questioned as to this. Dr. Lomax further said he considered that under the present law people could be far too easily put away in asylums and kept there, and the medical superintendent's powers were too autocratic. He proposed that there should be at first a single medical certificate, called a preliminary detention certificate, to be required in the case of any person with suspected mental disorder before he could be admitted into a mental institution, and it should give the medical officer in charge of the institution power of detention for three days. This certificate should be signed by the usual medical attendant, and it could be supplemented, if desired, by a second certificate. He thought it was absurd to suggest that two doctors should not consult before issuing a certificate; the objection was not made in the case of bodily illness. A second certificate should be required after 28 days, if the patient had not meantime been discharged, and this should be signed, where possible, by a diplomat in psychological medicine, and counter-signed by a magistrate. He did not think it was desirable that a patient should know all that was on the medical certificate, but he could be told the general reasons why he was being detained. He, the witness, believed that people would sooner have their liberty safeguarded than feel they were tending towards cure, although he realised cure would bring liberty. His great point, he said, was that every mental patient should have 28 days in a sort of half-way house for observation and preliminary treatment. Such places should be separate institutions, but he realised the practical constructional difficulties. The fresh air of mental institutions would be preferable to the surroundings of large general hospitals in cities. Voluntary boarders entering these observation buildings should sign a document conferring the right of detention for 28 days, so as to safeguard from a sudden attack of insanity of an impulsive character.

The Chairman said he had been very favourably impressed with the graduated system adopted in the case of recovering patients at Ewell, where there were a series of villas.

Dr. Lomax cordially agreed with the suggestion that there should be district commissioners of the Board of Control, vested with powers of supervision, and subject to the central board. It would add greatly to visiting efficiency. Speaking of private asylums, he said he had been to see patients in private asylums, and all those he had seen were quite well conducted. He believed that the private asylums of

England were conducted as well as were those in any part of the world. His objection to private asylums was the presence of the financial motive. He agreed, however, that a good recovery-rate, which was universally sought after, did not support an allegation of a financial motive for keeping patients after they had recovered.

The Chairman questioned the witness on his statement that owing to the absence of safeguards doctors were refusing to certify to insanity at all, and Dr. Lomax replied that the system he suggested, of first having the patient under observation, would only require that the doctor should certify a case as detainable for a time. The Chairman rejoined that this would still fail to prevent the doctor being shot at, and the witness agreed.

The next meetings will be held on March 10th and 11th, at 5, Old Palace Yard, Westminster, at 10 A.M. each day.

MEDICINE AND THE LAW.

MEYRICK v. DYSON.

BEFORE the Lord Chief Justice and a special jury, Dr. F. R. H. Meyrick sued Mr. F. C. Dyson, a provision merchant, of Stoke Newington, for £125 10s. 5d., as a balance due for medical attendance, board, and lodging for the defendant's son, Herbert Dyson, and for money paid on his behalf. Dr. Meyrick treated Herbert Dyson, who had been certified, from July 25th to Oct. 2nd, 1923, at his house in Ennismore-gardens, which was mainly used as a home for the treatment of nervous disorders, but in which he was permitted by the Lunacy Commissioners to receive one certified patient. The defence and counterclaim of the defendant alleged that the patient was to occupy a certain bedroom and be treated at 12 guineas a week under a verbal agreement, and that there had been breaches of the agreement and negligent and unskilful treatment in the following respects: that the patient had been moved to a small bedroom in an attic and given a bed too short for him; that the plaintiff had improperly administered hyoscine and morphia; that he had placed him unlawfully under mechanical restraint, and had kept him locked in his room, and alone; that he had not provided proper medical attention or food, and that the staff of nurses and servants was inadequate; that he was not taken out of doors and given sufficient exercise; that the plaintiff was frequently under the influence of drink and was unfit to be entrusted with the care of a person of unsound mind; that he kept the patient under drugs in order to save himself trouble and expense. The counterclaim was for damages for deterioration of the health of the patient in consequence of the above.

After a trial lasting nine days certain questions were left to the jury, whose replies are given below. The Lord Chief Justice, it will be seen, reserved judgment.

The Case for Dr. Meyrick.

In opening the case for Dr. Meyrick, Mr. J. A. Hawke, K.C., gave an outline of the story of the patient's detention in the plaintiff's house and of the evidence to rebut the charges made by the defendant. He pointed out that the more serious of these related to the alleged drunkenness of the plaintiff, and to the improper use of drugs in treating the case.

Dr. Meyrick, giving evidence, described his qualifications and the nature of his house, and stated that his cases came from all the leading specialists of Wimpole-street and Harley-street, and that Mr. Dyson had said that he had been recommended to come by Sir Maurice Abbot Anderson. He had originally agreed to take the patient for 12 guineas a week, but it had been verbally arranged at an interview on August 9th that this should be raised to 15 guineas. He, Dr. Meyrick, had been told the case was a mild one. He had no padded cell, had only used

wristlets and anklets on one patient, and had never used them on Herbert Dyson. The patient, who was 22 years of age, 6 ft. 2 or 3 in. tall, and weighed more than 12 st., had put on 5 lb. under his care; he was not fit to be sent out walking owing to his behaviour. To the witness's knowledge he was never locked in his room. A list showed that morphia and hyoscine had been injected on eight occasions, and on 17 hyoscine alone in mild doses. On Oct. 2nd, when the patient was removed, his parents were present and allowed themselves to be seen, which made the patient very violent, and at the father's request the witness administered an injection. There were four women nurses. Asked whether he was ever under the influence of drink, the witness answered "Never."

Cross-examined by Mr. J. D. Cassels, K.C., Dr. Meyrick said that chairs were used temporarily to lengthen the bed in the upper room to which the patient was removed when the other room proved unsuitable. Entries of "hypo-injection" in the report book for "hyoscine" were an omission by the nurse not intended as concealment. He did not know that hyoscine was not used at asylums such as Hanwell. Mr. Cassels stated that the report book showed 48 injections in 28 days and asked "would you accept it from me that such an amount and frequency of hyoscine and morphia treatment is unusual in a case of dementia præcox?" The witness answered, "No, I would not."

In answer to further cross-examination, Dr. Meyrick denied that wristlets or anklets had ever been used on Herbert Dyson, or that he had helped to put them on. He believed that a similar allegation was being made against him in another action by a woman patient. He said that if such restraint was used it had to be entered in a book in the case of uncertified patients, and denied that all such use was forbidden. The witness was cross-examined at length on the diet supplied, and of the recurrence of "cow's head" or bullock's head in the dietary. He stated that a nurse named Podd had been dismissed as not capable of looking after Herbert Dyson. He denied having ever returned home intoxicated, and put his arms round nurse Podd or kissed her. He never swore at the servants and never was drunk in his life. He admitted a conviction followed by a fine and suspension of his driving licence for being drunk when in charge of a motor-car, but denied that he was in fact drunk on that occasion. For his present action he had gone to the Medical Defence Union and retained Messrs. Hempsons to act for him, but had since changed his solicitors.

Dr. J. S. Risien Russell said that he had known the plaintiff for 20 years and had placed patients in his care, one being with him now. He had never seen anything wrong with the conduct of the plaintiff's home or heard patients complain. He believed Dr. Meyrick to be competent and had never seen him under the influence of drink. He had seen the patient Dyson before August, 1923, on three occasions. He then suffered from neurasthenia with symptoms of further trouble to come. Dr. Russell said that the use of sedatives depended on the state of the patient. In his opinion it was better to use them than to let the patient be terrorised by hallucinations day after day. It was far better in that class of case to employ sedatives than physical restraint. In his opinion, assuming his state to have been as alleged, the treatment of Herbert Dyson had been quite proper. Cross-examined, Dr. Risien Russell said that he considered hyoscine one of the most important remedies, most valuable at proper times in proper cases and proportions. He admitted a considerable difference of opinion among medical men as to its use, and regretted efforts, of which he had read, to do away with the use of it in asylums. It was preposterous to rob medical men of one of their most merciful and useful medicines, there being no alternative to hyoscine and morphia but physical restraint in violent mental cases. The alternative

in a certifiable case was to certify and place the patient in an asylum where there would be padded cells. He could not imagine anything worse than holding down by physical force or using a strait-jacket. As to wristlets and anklets, they might quickly subdue a patient who if held might feel he could get away. He agreed that they were not now employed for certified patients. He admitted that this view implied that they might be used in the case of a person of unstable or unsound mind indulging in violence, though not permitted for a person who had been certified. He would not have advised that Herbert Dyson should be kept alone in a room with the door locked. The short bed he would think right only as a temporary measure.

Dr. J. F. Woods gave evidence, in which he expressed approval of the use of morphia and hyoscine for violent patients.

Dr. J. C. Vaughan had attended at Dr. Meyrick's house in his absence and had given an injection of hyoscine and morphia to Herbert Dyson, who had attacked a nurse and had locked himself in his room.

Dr. E. W. Hedley said that he knew the plaintiff well, and had never seen him the worse for drink.

Dr. E. P. Scott had visited Herbert Dyson by the instruction of the Board of Control four times: on the last occasion the patient was not so well as on the first; he might have told the patient's mother that he had deteriorated. Personally he was against the use of hyoscine and other drugs, but had occasionally administered morphia and heroin. Cross-examined, Dr. Scott said he did not see the special book relating to seclusion, and did not see wristlets or anklets. He had entered in his report that there had been no seclusion, and must have been told so by nurses. He had to rely upon hearsay. In reply to the Lord Chief Justice, the witness agreed that superintendence such as his ought not to be exercised in a perfunctory manner. Dyson was the first patient he had visited thus. He had seen reports as to hyoscine and morphia being used, and had agreed with Dr. Meyrick that as the patient was going on satisfactorily the treatment should continue. He had not himself seen young Dyson in a condition in which drugs were needed, but relied on Dr. Meyrick who was in charge of the case. He had once asked about the dose, being biased against hyoscine, and had been told that the patient had been violent.

Dr. Mary Scharlieb had known Dr. Meyrick for about 15 years, and had visited his house. She thought him competent, and said that there was no ground for suggesting that he was given to drink. She thought the food must be good, as his patients had done well. She had not the slightest doubt that if the case were one of dementia præcox it was necessary to administer hyoscine and morphia. She would have administered them in the circumstances recorded in the manner in which they had been administered. There was nothing recorded to suggest that they had been used to save trouble.

Mrs. M. Miller, a nurse in the home, said that she had administered hyoscine and morphia to the patient under Dr. Meyrick's instructions. The food was good. It was not true that Dr. Meyrick was ever the worse for drink. Dyson had never been locked in his room or strapped down in his bed. Cross-examined, she said that wristlets and anklets had been used in "two other cases besides Mr. Dyson," and immediately corrected this statement, and said that they were never used for Mr. Dyson. She said she had made a mistake in saying "besides Mr. Dyson." She had never heard of their being used for him.

Several lay witnesses were called who had been treated or had had relatives treated, and who were thoroughly satisfied with the food, and had never seen Dr. Meyrick under the influence of drink. Captain Beddington had known Dr. Meyrick six years at his house and at his club; he had never seen him under the influence of drink. He had eaten good meals at Dr. Meyrick's house.

The Case for the Defendant.

Mr. Cassels opened the case for the defendant, laying stress upon the administration of drugs as being entirely improper, and upon the allegations of strapping down and of locking the patient in his room.

Mr. Dyson gave evidence as to the previous history of his son's case and his arrangements with Dr. Meyrick. He denied that on his first visit after his son had been received in the home Dr. Meyrick had complained of his son's habits, or said he must remove him to another room, or that he must raise his fees from the sum of 12 guineas per week originally agreed to 15 guineas. He denied that he had been told that the case was not suitable for Dr. Meyrick's home; he had been told that an extra nurse was required at 3 guineas a week and had refused to pay it. He stated that Mrs. Dyson had complained on Sept. 22nd of her son being drugged, and that Dr. Meyrick had been very angry. He described the scene at the removal of his son on Oct. 2nd, when he had asked Dr. Meyrick to give him a sedative as he was very violent, and had been made to sign a paper first requesting him to do so, as well as an undertaking to pay 5 guineas, because the plaintiff said his house was being disturbed. This claim was withdrawn in court by the plaintiff's counsel, his Lordship pointing out that in any case it had been made. Mr. Dyson stated that since leaving Dr. Meyrick his son had been better physically but not mentally. He criticised the accounts as to food to the effect that the prices showed that it could not be good. In cross-examination he said he had not removed his son sooner because he had not thought of doing so.

Mrs. Dyson, the patient's mother, in giving evidence, said that she had visited her son several times. She had not been satisfied with his accommodation. She had found him on Sept. 11th in bed in a dazed condition, and on another occasion outside his room refusing to enter it. She ascribed this to his wish to see life outside. He had shown her the marks of hypodermic injection on his arm. He was much better and had gained a stone since leaving Dr. Meyrick. Under cross-examination Mrs. Dyson said that her son was always more or less dazed and stupid when she saw him. She had not at first suspected the cause of this.

A brother of Herbert Dyson described the scene at his brother's removal from Dr. Meyrick's house.

Miss E. C. Podd, giving evidence, said that before going to Dr. Meyrick's in July, 1923, she had had four years' experience as a mental nurse. She sometimes took Dyson out for a walk; he gave no trouble but wanted to stay out longer, and once suggested having tea out. She was on night duty (9 P.M. to 9 A.M.) for three weeks from August 11th. She remembered Dyson having hyoscine and morphia injections, 42 in 28 days out of 69 days that he was in the home. She had used anklets and wristlets on four patients, including Dyson, always by Dr. Meyrick's instructions. She had found Dyson restless and walking about his room at night on August 9th; had got "the straps" by Dr. Meyrick's orders, and he had helped her to put them on the patient, after ordering him into bed. His hands and feet were put in the straps which were tied under the bed with webbing. They were used two or three times while she was on night duty, and she was told by Dr. Meyrick to use them if she had any difficulty. This was because the patient used to get up and walk about and switch on the electric light or look out of the window. The door of Dyson's room, as a rule, was locked, and the key kept on a ledge outside the door. Dr. Meyrick had told the nurses to lock it. There was no bell to the room; the patient had to knock on the door to attract attention, and he was visited by a nurse when there was an opportunity. On August 15th, at 5 A.M., he got up, broke a window and leaned out. She persuaded him to come in without trouble, after which Dr. Meyrick gave him an injection. She had told the plaintiff of Dyson's

wish to have tea out, and also to play the piano, but nothing was done. [At this stage the jury inspected the plaintiff's house.] Continuing her evidence, Nurse Podd said that on one occasion the patient attacked her in his room, took the key of it from her by force, and locked her in the room. She was certain that she had seen Dr. Meyrick intoxicated twice. On one occasion after attending a wedding he had smelt of drink, and had put his arms round her on the landing and kissed her. She had resisted and had afterwards told another nurse, Sister Charteris, what he had done. She spoke of another occasion when he had put his arm round her and called her endearing names over the banisters. Cross-examined, she said she knew of the duty to record the use of mechanical restraint, and that it was not right to lock a certified patient in his room. She had reminded Dr. Meyrick of the duty to write in the restraint book, and he had said that he did not keep one. He had told her not to enter it in her report book.

Miss R. Thompson, formerly a nurse at the plaintiff's house, said that she had gone into Dyson's room on one occasion in the morning and found him with his arms strapped. His door was always locked. In her opinion the food was very poor. She had seen Dr. Meyrick several times the worse for drink while Dyson was under his care. Cross-examined, she denied that she had been dismissed, saying that she had left because she thought the house was not a place where a decent girl ought to work, and on account of the company brought in at night by Dr. Meyrick.

Miss N. Charteris said she was a nurse at Dr. Meyrick's house while Dyson was there. His door was kept locked by Dr. Meyrick's instructions. She had been present when hyoscine and morphia were injected. They produced stupor for three or four hours, during which time nursing attention was not required. The plaintiff had complained, she said, of the expense of Dr. Vaughan being called in, and had said to her of Dyson, "Drug him well; you cannot kill a lunatic." She had seen Dr. Meyrick several times under the influence of drink. She had left without notice because the plaintiff had sworn at her, also because he ordered her to do things that were wrong.

Miss K. Pearce, parlourmaid and later cook at Dr. Meyrick's house from July 6th to Oct. 6th, 1923, described the food supplied for which a standing order had been given. She stated that Dr. Meyrick was often under the influence of drink, and that she had left because he had when in that condition used bad language to her in the kitchen.

Dr. F. Dillon described the condition of Herbert Dyson when at Northumberland House Mental Hospital as dull and mentally confused at first, but improving later, when he could play draughts and dominoes, and play on the piano. He had been given sedatives there, and hyoscine on one occasion.

Dr. Dillon described hyoscine as a powerful drug of uncertain action only to be used in emergency. He saw nothing in the reports of its use by Dr. Meyrick in the nature of evidence of excitement or of conditions that would render its frequent administration advisable. Hyoscine had been commonly used at one time, but was now discontinued in mental hospitals, as the opinion of medical men was against it. Asked by the Lord Chief Justice to define what he meant by the opinion of medical men, the witness explained that he meant the opinion of the majority. Some remained of the opposite opinion, but medical men in mental hospitals were opposed to the use of the drug, while those treating patients outside were in favour of its use. It was a question of experience. Cross-examined as to the evidence given by Dr. Risien Russell, the witness said that he gathered that Dr. Russell had said that the alternative to the use of hyoscine was a padded room and to let the patient exhaust himself. That was nonsense, as there were other alternatives to hyoscine. He admitted that at Northumberland House Dyson had been violent,

doing damage, and also assaulting a medical officer. He had also had delusions, and had sometimes needed six attendants to restrain him. The doses recorded at Dr. Meyrick's were not excessive.

Dr. R. H. Cole confirmed generally evidence given by Dr. Dillon. He had not seen the patient, but had read Dr. Meyrick's report book. He never used hyoscine except in a case of emergency. It paralysed and produced hallucinations. It interfered with nutrition, and he had never employed it in a case of dementia præcox. The case of Herbert Dyson seemed to the witness to have been a bad case unsuited for treatment in a private house. It would be very bad for a patient with dementia præcox to be kept in one small room. The diet at Dr. Meyrick's did not appear to be generous. Under cross-examination Dr. Cole said that in a case of dementia præcox it might be dangerous to take a patient out, and that Dyson would have required a man on each side of him, and exercise in a garden. His case was not suitable for London. Asked as to whether many medical men did not think it proper to use hyoscine in cases of excitement, he replied that there were a few who thought so. He considered that Dr. Meyrick should have advised the father to have his son removed, and should have gone to the Board of Control if he refused. In the alternative he should have changed his drugs. Dangerous drugs should not be given day after day for three weeks.

The Judge's Summing-up.

The Lord Chief Justice, in summing up, suggested that there was a question whether it was desirable that private individuals should be allowed to undertake the detention of human beings for profit. The jury, however, were dealing with the difficult case before them and not sitting to inquire into the Lunacy laws. The burden of proof as to the allegations of breach of duty was on the defendant, who was entitled to expect a reasonable performance of his contract in every part of it, food, lodging, medical care, and attention. The allegations of the defendant affected many points, and the jury might think that where everything was complained of they could not pay much attention to a complaint about anything. The question of food had provoked humour, but food was no laughing matter for people who had to live in establishments of the kind described. The food of a first-class hotel was not, however, to be expected in a nursing home, and might not be suitable. His Lordship criticised the system adopted of working out averages of diet from the food accounts produced. It was impossible to exaggerate the importance of the matters at issue, particularly with regard to mechanical restraint and confinement. As to this they had to ascertain what was actually done in the case before them. With regard to the use of drugs, it was not for the jury to decide between rival schools of treatment. The allegation on the part of the defendant was that the drugs administered to the patient in question on the scale, with the frequency, and in the circumstances shown, were not genuinely dictated by the medical needs of the patient's case, but were suggested by the interest and convenience of those administering them. With regard to mechanical restraint, Lord Hewart pointed out that its employment was unlawful under the Lunacy Act, 1890, except in specified circumstances and with a record kept of its use. No entry as to the use of mechanical restraint appeared in Dr. Meyrick's register. If, therefore, the anklets and wristlets produced had been used for Herbert Dyson their use was unlawful. The instruments that might be used were set out in detail. It was suggested that if used they had done no harm. The plaintiff had stoutly denied that they had been used on Herbert Dyson, but had spoken of the effect that they produced when employed as mesmeric. The patients upon whom wristlets and anklets were used might resist other things, but were mesmerised by them. That, his Lordship said, was very signi-

ficant. Discussion took place upon a question raised by the jury as to whether they could find that the straps had been used, but not by Dr. Meyrick's orders. His Lordship said that no suggestion as to this had been put to the nurses when they gave evidence, but that if the jury came to the conclusion that they had been so used they might say so. With regard to the locking of the patient in his room, he directed them that this was seclusion and should have been recorded, but that this had not been done.

Questions Answered by the Jury.

Lord Hewart concluded by leaving to the jury a series of questions, to which, after three and a half hours' deliberation, they returned answers as follows:—

1. Did the defendant agree that the weekly payment to the plaintiff should be raised to 15 guineas?—No.

2. Was the plaintiff guilty of negligence or breach of duty in the matter of—

(a) the bedroom or the bed?—No.

(b) drugs?—No.

(c) medical attention?—No.

(d) food?—No.

(e) staff of nurses and servants?—No.

(f) drink?—No.

(g) confinement to bedroom and seclusion?—Yes; in that the door was at times locked, and the times not entered in the necessary book.

3. Were the anklets and wristlets put upon Dyson—

(a) under the plaintiff's instructions?—No.

(b) not under the plaintiff's instructions?—No.

His Lordship then told the jury that by their answer to Q. 1 the plaintiff's claim was reduced to £98 4s. 6d., and that they must now say by what amount that sum must be reduced owing to their finding as to the seclusion of Herbert Dyson in his room (Q. 2 (g)). The effect upon him of that seclusion, his Lordship said, was highly problematical. While the jury were absent considering this question, argument took place upon the findings set out above, as to whether the illegal seclusion and the failure to record it (Q. 2 (g)) did, or did not, go to the root of the contract, so as to disentitle the plaintiff from recovering anything. The jury having found that owing to the seclusion of the patient and the failure to enter it, the plaintiff's claim should be reduced by 20s., it was alternatively submitted on behalf of the plaintiff that he should have judgment for £98 4s. 6d. and costs of the issues on which he had succeeded, and on behalf of the defendant that if the plaintiff were held to be entitled to recover anything, the defendant should still be entitled to judgment for the 20s. under Q. 2 (g) with costs, and to the costs of the issue relating to the claim for additional weekly payments (Q. 1).

His Lordship intimated that the questions raised were of great importance and reserved judgment.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 21st, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 149; scarlet fever, 1696; diphtheria, 1025; enteric fever, 48; pneumonia, 1473; puerperal fever, 34; cerebro-spinal fever, 13; acute poliomyelitis, 6; acute polioencephalitis, 1; encephalitis lethargica, 58; continued fever, 1; dysentery, 13; ophthalmia neonatorum, 124. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases showed a decrease of one from the number for the preceding week. Thirty cases were notified from Derbyshire, 31 from Northumberland, 13 from Notts, 49 from Yorks, North Riding (Middlesbrough, C.B., 47) and 15 from Yorks, West Riding.

Deaths.—In the aggregate of great towns, including London, there were 3 deaths from enteric fever, 76 from measles, 11 from scarlet fever, 130 from whooping-cough, 35 from diphtheria, and 352 from influenza, as compared with 354, 291, 202, and 195 in the four preceding weeks. In London itself the deaths from influenza numbered 88, from whooping-cough 45, and from diphtheria 8.

THE ORAL ADMINISTRATION OF GLUCOSE.

To the Editor of THE LANCET.

SIR,—The observations of Dr. T. Izod Bennett and Dr. E. C. Dodds on the Oral Administration of Large Quantities of Glucose, and its Therapeutic Uses (THE LANCET, Feb. 28th) lend new support to the established practice of sugar feeding in conditions in which other foods are poorly assimilated. Sir William Osler, in the "Principles and Practice of Medicine" (eighth edition), advocated liberal carbohydrate and sugar feeding in typhoid fever some years ago. I agree, however, that the amounts employed are usually much too small. In a paper entitled the Value of Sugar in the Treatment of Typhoid Fever,¹ I drew attention to the importance of giving large quantities of sugar in febrile illnesses and laid particular stress on (1) its ease of assimilability, (2) the readiness with which patients take it, and (3) the counteraction of acidosis which it achieves. My observations were made on a large number of typhoid cases among Belgian refugees. I employed ordinary cane-sugar in quantities varying from 6 to 10 oz. a day in addition to other carbohydrate in the form of biscuits, chocolate, and bread given as bread-and-milk, and I was able to compare clinical results in my own cases and in other cases treated with the old-fashioned milk régime. I concluded that the liability to grave acidosis, to serious wasting and bedsores, and to muscular weakness and tachycardia during convalescence was appreciably diminished by a liberal ration of sugar, and that from 500 to 1000 calories per diem could readily be supplied in this form. Since then I have always urged a liberal use of sugar (as cane-sugar, glucose, or lactose) in prolonged fevers and pneumonia. It may also be helpful in some cases of heart failure. I have also shown² that a solution of cane-sugar produces an inconsiderable rise in gastric acidity when given as a test-meal and for this reason suggested its use in ulcer dietaries. I have not, however, employed it in cases of under-nutrition such as Drs. Bennett and Dodds describe; in such cases, and particularly in those with a psychoneurotic basis, it is presumably preferable to insist, as soon as possible, on a mixed dietary, but sugar in some form should be valuable initially in helping to overcome the general weakness and the associated anorexia. The cane-sugar was consumed with avidity by my typhoid patients, whom I frequently saw scooping the remaining grains from the bottom of their cups. The calorie-value of cane-sugar is higher than that of commercial glucose (10 oz. giving 1000 calories) so that smaller quantities can be used, and with sugar at 7d. to 8d. per pound the cost is about the same or slightly less.

I am, Sir, yours faithfully,

Wimpole-street, W., Feb. 28th, 1925.

J. A. RYLE.

RHEUMATISM AND GOITRE.

To the Editor of THE LANCET.

SIR,—Perusal of your interesting annotation *re* "Cancer and Goitre" in THE LANCET of Feb. 14th reminds me that still more cogent evidence exists in favour of the possibility that a common factor may be involved in the incidence of goitre and rheumatism; and that a state of *hypothyroidism* favours the development of rheumatism.

The recent report of the Ministry of Health on the "Incidence of Rheumatic Diseases" reveals that alike in acute rheumatism (rheumatic fever), sub-acute rheumatism, cardiac rheumatism—muscular types as well as rheumatoid arthritis—the incidence is higher in *females* than males, and the same

¹ Guy's Hospital Gazette, Nov. 6th, 1915.

² Guy's Hospital Reports, 1921, lxxi., 158.

is true of osteo-arthritis in the later decades. As to rheumatic fever, it states: "Not only are our insured females from 16 to 24 attacked much more frequently (as 5 to 3) than insured males of similar age, but that in the next age-group, 25 to 34, females are attacked three times as often." The incidence of rheumatism between 10 and 15 years is higher also in girls than boys. That of rheumatoid arthritis, and to a lesser extent of rheumatic fever, is heaviest in the child-bearing decades, and of osteo-arthritis at and after the menopause.

In respect of *goitre*, too, we find the same preponderant incidence in females from childhood right up to the menopause with its maximum in the child-bearing decades. In short, the periods of increased incidence of rheumatism and *goitre* synchronise markedly with puberty, the child-bearing decades, and the menopause—viz., with those physiological processes menstruation, pregnancy, lactation, which determine oft-recurring or enduring hyperæmia of the thyroid. The increased incidence of *osteo-arthritis* in females at the menopause is doubtless dependent on the senile atrophy of the thyroid incidental to this epoch. Clinically speaking, the association between "rheumatism" and thyroid deficiency is intimate. The "rheumatic" child often shows minor signs of hypothyroidism. Again, rheumatic fever is often followed by a state of hypothyroidism, and I have noted the following peculiarities suggestive of a link with *goitre*. First, that in regions where *goitre* is endemic, the incidence not only of rheumatic fever and cardiac rheumatism, but of rheumatoid arthritis appears to be abnormally high. Secondly, that if rheumatic fever develops in the child of a *goitrous* mother it shows a strong impetus to chronicity, being rebellious to salicylates. Also, if it occurs in the child of a mother not necessarily *goitrous*, but resident in a region where *goitre* is endemic, it may show the same peculiarities. Thirdly, that this obduracy to salicylates relents if *thyroid* be superadded, the thyroid seeming to activate the otherwise impotent salicylates. As to rheumatoid arthritis and osteo-arthritis their association with hypothyroidism and often with *goitre* is well established, as also their favourable response to thyroid therapy.

As to geographical incidence, the findings of the report are somewhat suggestive. Thus, the death-rate from rheumatic fever and cardiac rheumatism is much higher in the North-West and South-West than in the East and South-East Counties. It is highest in Lancashire and lowest in Norfolk, but the former again falls below certain Welsh counties, notably Glamorgan. Finally, what is most arresting is that the death-rate in females from rheumatic fever and cardiac rheumatism in Bristol is immensely high even compared with Lancashire. The Cotswolds, the Mendips, and the valleys of the Pennines are all noted haunts of *goitre*. Now, Bristol lies partly in Gloucestershire and partly in Somersetshire, both counties in which *goitre* is endemic. Again, the river Avon on which it stands rises in the Cotswolds, coursing thence through Wilts and Somerset, and *goitre* is certainly endemic in some of the villages on or near its banks. This excessive incidence of rheumatic fever and cardiac rheumatism in a city lying in a *goitrous* district, and this among the female population, is very arresting. Viewed in light of the fact that rheumatic fever in children of the *goitrous* or those residing in endemic areas is rebellious to salicylates, but responds if thyroid be superadded, seems to suggest some ætiologic connexion between the heavy incidence of acute and cardiac rheumatism in Bristol, and the endemicity of *goitre* in the environs. The high death-rate of itself seems to predicate lack of response to salicylates, and presumably this obduracy must be due to some inherent defect in the female victims. May it not be that the females of the city are handicapped by an excessive liability to thyroid inadequacy or hypothyroidism? Hypothyroidic women tend to bear hypothyroidic children, and my experience

leads me to believe that hypothyroidism connotes a special liability to rheumatic affections. Turning to Glamorgan, whose death-rate exceeds that of Lancashire, we find *goitre* endemic on the Barry Estuary; and again, Lancashire traversed by the Pennine range is also the seat of scattered foci of endemic *goitre*. On the other hand, the lowest incidence of rheumatic diseases is in Norfolk, Cornwall, and Anglesey, and as far as my information goes they seem exempt from endemic *goitre*. As to rheumatoid arthritis and osteo-arthritis their predominant incidence appears to be in regions traversed by the Cotswolds, Mendip, and Pennine ranges.

Further inquiry is obviously necessary, but I submit that the evidence adduced is such as indicates that here is a line of investigation that might throw a flood of light on the much needed prophylaxis of rheumatic fever and cardiac rheumatism.

I am, Sir, yours faithfully,

LLEWELLYN J. LLEWELLYN.

Upper Brook-street, W., Feb. 26th, 1925.

THE ACIDIC VALUE OF THE URINE IN SKIN AND OTHER MANIFESTATIONS.

To the Editor of THE LANCET.

SIR,—I had hoped that I had made it clear in my article in THE LANCET on Feb. 7th that I was working on the concentration of the hydrogen ions only, but Dr. Whitfield's criticism of it in your issue of Feb. 14th and also numerous letters that I have received have shown me that some readers of it have misunderstood me.

I have not been working on the amount of acid in the urine, I discovered long ago that this was not increased. I used the phrase "acidic value" so as not so frequently to reiterate the words "hydrogen-ion concentration" and "pH value," but it means the same thing. The tests, which now number some thousands, were carried out for me by two first-class biochemists, working independently, using the Clark and Lub colorimetric method, the results being checked electrically, showing that they were chemically and mathematically accurate.

If Dr. Whitfield will get his biochemical friends to work out the hydrogen-ion concentration of the urine in his cases of acne and seborrhoea he will find that 100 per cent. will give an abnormally high concentration. It is not a question of my opinion but a definite scientific fact which is very easily proved. Litmus is useless as an indicator for this kind of work, its range is too narrow, and has been given up by biochemists for nearly 20 years.
